

Volume 74 Number 1

JANUARY 1959

Preparedness and survival.....

Leroy E. Burney

70 newly recognized viruses in man..... 6

Robert J. Huebner

Local health departments: growth or illusion?..... 13

Barkev S. Sanders

Nursing services outside the hospital for cardiovascular
disease patients..... 21

*Margaret Denham, Sidney Abraham, and L. M.
Graves*

Diagnostic and therapeutic X-radiation in an urban popu-
lation..... 29

Abraham M. Lilienfeld

Medical radiation..... 36

Radiation research. Conference report..... 39

Milk contamination in the Windscale incident..... 42

Arthur H. Wolff

Reactivity of the RPCF test in leprosy compared with
other syphilis tests..... 45

*George R. Cannefax, Sister Hilary Ross, and Huldah
Bancroft*

Acute intestinal infection in Alaska..... 49

John E. Gordon and Frank L. Babbott, Jr.

Continued ►

frontispiece

In the radiological counting room at the Robert A. Taft Sanitary Engineering Center of the Public Health Service, technicians measure the radioactivity of samples of milk, air, and water.

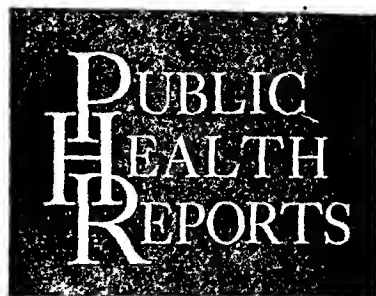

Seasonal study of enteric infections in Alaskan Eskimos...	55
<i>H. J. Fournelle, Virginia Rader, and Clarissa Allen</i>	
Detecting poliovirus in vaccine lots used in Idaho in 1955.	60
<i>Carl M. Eklund, William J. Hadlow, Edgar G. Pickens, and Robert K. Gerloff</i>	
Highlights of the Social Security Amendments of 1958....	67
<i>Lucy M. Kramer</i>	
A migrant labor crisis in Immokalee.....	77
<i>Wilson T. Sowder and Joseph Lawrence</i>	
Sanitary engineering degrees awarded in 1957.....	81
<i>Frederick K. Erickson and Frank A. Butrico</i>	
Status of mosquito-borne encephalitis in the United States.	84
<i>Leslie D. Beadle</i>	
Cancer morbidity in the United States.....	91
Short reports and announcements:	
WHO report on health statistics.....	5
Regular Corps examinations.....	12
Medical education group formed.....	20
Signs and symptoms.....	28
First annual NHS report on illness.....	41
Certain food additives listed as safe by FDA.....	43
International mail pouch.....	44
New clinical neuropharmacology research center.....	54
Research, construction, and training grants.....	59
Social Security Administration seeks eligibles.....	66
National conference on homemaker services.....	80
Division of Public Health Nursing.....	83
Public Health Service traineeships.....	92
Publications.....	93

Published concurrently with this issue:

PUBLIC HEALTH MONOGRAPH No. 56 . . . Morbidity from cancer in the United States.

Harold F. Dorn and Sidney J. Cutler

207 pages. A summary and information on availability appear on pages 91-92.

LEROY E. BURNET, *Surgeon General*

Preparedness and Survival

SURGEON GENERAL LEROY E. BURNEY

IN his book, *Year of Decision*, Bernard de Voto wrote: "Sometimes there are exceedingly brief periods which determine a long future. The limb of a tree grows to a fore-ordained shape in response to forces determined by nature's equilibriums, but the affairs of nations are shaped by the actions of men, and sometimes, looking back, we can understand which actions were decisive."

De Voto's year of decision was 1846, a year of westward march and external crisis for the United States. Nowadays, events move at a swifter pace. In the turbulent world of the mid-twentieth century, every year is a year of decision.

Yet there are areas of demarcation and resolution which can be fixed firmly in a period of time. One such area is civil defense and the time is the present. For 1958 has been a year of decisive action in national civil defense and mobilization, that is, all the civilian activities undertaken for preparedness, survival, and recovery in time of war or emergency.

Actions taken by the President indicate the high priority he places on civil defense and mobilization programs in the Federal Government:

- Reorganization Plan Number 1 of 1958 coordinates the Federal Civil Defense Administration and the Office of Defense Mobilization into the Office of Civil and Defense Mobilization (OCDM). Central direction will reside in the Executive Office of the President.

This article is the substance of an address delivered by Dr. Burney before the 86th annual meeting of the American Public Health Association in St. Louis, Mo., October 28, 1958.

- The President will delegate specific civil defense responsibilities to various Federal agencies with policy determinations and coordination by OCDM, under the direction of the Honorable Leo A. Hoegh, former Governor of Iowa. The Public Health Service will be responsible for health and medical care operations.

- A new national plan for civil defense has been developed, spelling out principles and general strategy.

In sum, the entire civil defense and mobilization effort will be stepped up and given the kind of emphasis called for by these troubled times.

Civil defense is as urgent as tomorrow's newspaper headline and as near as a pushbutton. It cannot be shrugged away. It cannot be postponed until some indefinable date when we may be so generously supplied with personnel and resources that we can proceed in a leisurely fashion. That kind of future may never arrive. The dark specter of disaster—either natural or manmade—is an everyday possibility, hovering like an unwelcome neighbor just outside our door.

Are we ready for tomorrow's hurricane or flood or atomic explosion? If we as health leaders cannot answer that question with a resounding "Yes!" we are failing in our civic responsibilities. Medical and public health services for emergencies must be ready and they must be able to work. Leadership in civil defense planning is the strongest kind of evidence that the health personnel of this country have the safety of their fellow men at heart and are working to protect it.

To be sure, civil defense and mobilization are complex. There have been false starts and

Public Health Reports, published since 1878 under authority of an act of Congress of April 29 of that year, is issued monthly by the Public Health Service pursuant to the following authority of law: United States Code, title 42, sections 241, 245, 247; title 44, section 220. Use of funds for printing this publication approved by the Director of the Bureau of the Budget, August 24, 1957.

U.S. DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE

ARTHUR S. FLEMMING, *Secretary*

PUBLIC HEALTH SERVICE

LEROY E. BURNEY, *Surgeon General*

water plan, and the national biological and chemical warfare defense plan.

The national plan and its annexes will be our guide to civil defense principles and strategy. Actual operations, however, will depend very largely on local preparedness and effort. Federal planning is designed to develop the capabilities of local agencies and to coordinate the programs. But the States and communities must be ready to do the job.

We shall, of course, work closely with the States. We expect to rely on established relationships and to develop new ones. As in more familiar programs, the key to an effective civil defense program is a strong local-State-Federal partnership, backed up by the participation of professional and voluntary groups.

In particular, we plan to centralize our civil defense activities in a new division in our Bureau of State Services. This division will serve as a focal point for civil defense planning and operations.

In addition, I plan to invite a group of leaders to serve as an advisory committee on health and medical services for civil defense. National leaders in medicine, public health, civil defense, and public affairs will be asked to recommend courses of action for the Public Health Service and cooperating organizations.

As most of you know, a Division of Radiological Health has recently been established within the Service. We expect to draw upon the resources of this division in developing plans for radiation research, training, and protection. Studies in radiation monitoring and exposure and on radioactive fallout levels are already underway. These and similar studies should be of invaluable aid in devising radiological defense measures.

Other units of the Service will participate in civil defense operations which are geared to their normal programs. For example, the sanitary engineering and communicable disease control components of the Service will have primary responsibility for planning and action in their areas of competence. This concept of "built-in" civil defense is logical and desirable for agencies at all levels.

So much for what has been done this year and what the Public Health Service expects to accomplish in the months ahead.

The estimates of damage to this country from nuclear attack are all too familiar. So is the picture of utter chaos that can follow any type of enemy action in modern warfare: nuclear, conventional, biological, or chemical. You know as much of what has been said and written about these horrifying possibilities as I do.

You and I, with every other qualified medical and health worker have the duty to protect, insofar as possible, 175 million Americans from the effects of attack, when and if it comes. If we can disregard for the moment the picture of total war, it may be easier to think realistically of what we must do now, systematically month after month, year after year, in order to live up to our charge.

Interlocking Plans

In many ways, civil defense is an intensely local problem. In the event of enemy attack, individual areas may have to be on their own for weeks, especially if they have not been direct targets and have not sustained casualties. They would undoubtedly be cut off from normal channels of transportation, trade, and communications. Many communities will have to rely on their own resources to an unprecedented extent. They will have to develop a kind of self-sufficiency not within the recent experience of our American communities. They will also have to share their health and medical services with less fortunate areas.

Conversely, therefore, it is not enough to think of civil defense as a local affair. Your town, my town, will receive protection only insofar as the total health and medical resources of the Nation are planned, organized, practiced, and mobilized to come to its defense.

We must work at the basic components of civilian health and medical defense in a series of interlocking plans at local, State, regional, and national levels. These, in turn, will be developed in the same intimate relationship with other components of civil defense, such as communications, transportation, food supply, fire control, rescue, and postattack rehabilitation.

The basic components of civilian health and medical defense are:

- Development of a health and medical care plan, closely tied in with related service and resource plans.

changed signals. There have been gaps in staffs and in funds, and lack of a steady focus in civil defense work.

As a former State health officer, I have shared with you some of the frustrations of the past. There will probably be new ones in the future. We have been and will be confronted by vast and changing needs. Who could have known 2 years ago the challenges that confront us today—the new weapons, the mounting potentialities of warfare? We must be prepared every day to meet the unpredictable, the unknown.

Another Look at Civil Defense

The actions taken in 1958 are designed to correct past deficiencies at the Federal level. New appraisals of potential attack and a thoroughgoing administrative study led to the adoption of two important principles. The first is that the total civilian defense must be considered of equal importance to our military preparedness. The second is that mobilization and defense of civilian resources are inseparable and should be under the supervision of a single organizational unit of the highest stature and authority. This means not only the protection of the population in their local communities but also the management of all resources for production, procurement, and stabilization of the economy in time of war.

A basic concept of this plan is that civil defense functions should be planned and carried out by the Federal agencies best equipped to deal with them. The Office of Civil Defense and Mobilization will provide policy direction and coordination. The Federal agencies will be responsible for program content and operations.

In line with this policy, Governor Hoegh has indicated that broad responsibilities will be delegated to the Department of Health, Education, and Welfare, with the Public Health Service responsible for health and medical care. The delegation of authority, however, has not yet been made. In general we expect that it will include the following types of responsibilities:

- Overall planning and guidance of emergency health and medical services.

- Development of national medical casualty and preventive health services.

- Development of a national emergency water supply plan.

- Training of emergency health and medical personnel.

- Conduct of research in medical and public health emergency measures.

- Continuous evaluation of civilian health and medical resources and requirements.

These broad responsibilities, of course, will encompass such specific areas as radiation surveillance and protection of the civilian population against biological and chemical warfare agents.

In effect, therefore, the Public Health Service will plan and direct the health and medical components of civil defense and defense mobilization at the national level. To do this, we are already developing plans that will make all-out demands upon all of the Nation's health resources, both governmental and nongovernmental. The responsibility for casualty care is a tremendous one. It is the hard core of civilian health defense.

Two other important developments round out the story of this Nation's new look at civil defense in 1958.

The first is the enactment of P. L. 85-606, amending the Federal Civil Defense Act of 1950. Among other things, this amendment for the first time authorizes contributions to the States for the administration of civil defense services. State health departments will need to work with their State civil defense directors to see that a proper portion of funds appropriated under this authority is made available for emergency health and medical activities.

The second accomplishment is the issuance by OCDM of the National Plan for Civil Defense and Defense Mobilization. Just off the press and now being distributed, this plan is the basic document of civil defense. It sets forth the mission of each level of government and of the individual citizen. Each of us should become familiar with the plan and with its forthcoming annexes, which will cover all the special and auxiliary services essential to civil defense. The Public Health Service will have primary responsibility for developing the annexes on the national medical and health plan, the national

tional inventory of survival-type medical items located at wholesale drug outlets, warehouses, hospitals, and retail drugstores. The information developed from this study, to be completed early in 1959, will point up anticipated shortages of essential items.

Preparedness and survival in war are, of course, closely related to preparedness for natural disasters. Each year, hurricanes, floods, tornadoes, and other misfortunes kill and injure thousands of people, disrupt entire communities, and cause untold destruction of homes and property. Every disaster, every threat of disaster, should be used as a training ground for civil defense operations.

We in health and medical services should take advantage of what Secretary Flemming, in his former capacity as director of the Office of Defense Mobilization, calls the "positive impact" of natural disasters, wherein "the experience of fighting the disaster helps us to create the organizations and learn the techniques needed to fight the much greater disaster of war." By the same token, our capability of handling a hypothetical attack should stand us in good stead in responding effectively to the lesser problems of natural disasters.

Our Year of Decision

The great difficulty in civil defense work is that we are dealing with calculated guesses, with possibilities so awesome that they are difficult to accept. We must overcome our natural reluctance to admit such possibilities. The realities of today's world lead inescapably to

the conclusion that preparedness for civilian defense will be a part of our normal way of life for many years to come. If civil defense is seen as such a continuing responsibility, to be planned for and worked for on its own merits, public health can create and perfect the machinery that will help the people of this Nation withstand an enemy attack, recover from it, and press on.

It is my great concern that the Public Health Service provide a steady stimulus to planning, organization, and action in civil defense throughout the Nation in the months ahead. We, of course, can accomplish very little alone. I am gratified to learn that we shall begin with well-developed plans in many States. I am even more gratified by the action of several major professional organizations, without whom no national emergency health and medical service can be developed. The American Medical Association and the American Hospital Association, for example, both have strong civil defense committees prepared to join in national planning.

We in public health must become more sensitive to civil defense needs and we must develop both the competencies and a focus of organization and action. Civil defense is an interlocking job that calls for our greatest application of ingenuity, perseverance, and leadership. It is a challenge that we must meet now if we are to safeguard the Nation's future. We must make this our "year of decision," in which we chart a course of action to meet whatever emergencies the future may hold.

WHO Report on Health Statistics

The fifth report of the World Health Organization's Expert Committee on Health Statistics (No. 133) deals with the collection of statistics, organization of national committees, personnel training, cancer registers, and health indicators related to standards and levels of living.

A limited number of copies are available from the National Office of Vital Statistics, Public Health Service, Washington 25, D. C.

- Activation of the plan by means of a uniform organization and systematic practice in emergency health and medical exercises.

- Continuing training programs so that all health and medical workers will be instructed on new problems and new methods.

- A communications system so that all health and medical workers are kept informed of administrative and other developments.

The specific services which must be developed are closely related to our usual public health jobs: communicable disease control, sanitation, laboratory services, development of health facilities, and special services for mothers, children, and older people. In fact, these usual programs are our first line of health defense in any emergency. Underlying the total plan for civil defense and mobilization is the assumption that civilian health must be maintained and raised to higher levels if the Nation is to meet the stresses of war and withstand enemy attack.

Civilian health and medical defense, however, calls for something more than intensifying our present programs. It requires new organizational relationships and cooperation in a literal sense, that is, operating together. We have many cooperative programs for clearly defined goals. In civil defense, the goal may not be clear, but we must have specific actions at specific times and in specific places. So many physicians, dentists, nurses, engineers, sanitarians, and health educators will be expected to turn out at specific times and locations to carry out the duties they will be expected to perform in the face of disaster. They will be expected to repeat this performance until the response is automatic, smooth, and sure. Such a state of readiness must become a reality in every part of the country.

Every health agency, official and voluntary, every professional society, national, State, and local, should know where and how it can best function in an emergency. In public health departments, plans should be made for a second headquarters in case the first has to be abandoned. There should be well worked out lines of succession in key health jobs to assure continuity of leadership. Provision should be made for safe storage of essential records.

It is assumed that local health authorities are thoroughly familiar with health resources

in their communities. Civil defense planning requires that these resources be known at regional and State levels, and that this knowledge include resources outside the traditional health settings which may be drawn upon for health and medical services in an emergency.

Disaster Resources

Obviously, medical care will have to be provided for casualties. But what measures will be necessary to take care of illnesses when the supply of physicians is severely depleted? when there is an acute, often prolonged, shortage of medical and sanitation supplies? when medical facilities are damaged or greatly overcrowded? How can we handle the problems growing out of a limited food supply?

There is also the vital matter of personnel and training. Emergency planning calls for a nationwide reservoir of professional health manpower trained in civil defense knowledge and skills. We in the Public Health Service plan to work with universities, health agencies, and professional groups in increasing these skills. In this connection, we will work with the program of medical education for national defense under which grants are made to medical schools to incorporate into their curricula the new knowledge of military or civil emergency medicine and public health. Such assistance needs to be expanded both in amount and scope. For example, measures need to be developed for bringing the new knowledge to physicians already in practice, and to the other health professions.

In order to conserve the skills of the health professions in emergencies, the public must also be trained in first aid and home nursing techniques. Professional activities can then be limited to highly skilled tasks and supervision. The public, as well as the professions, must be prepared to live with austerity.

All types of supplies and equipment must be available and ready for use. In the field of health requirements, the Public Health Service will evaluate the needs for essential survival items and develop programs designed to assure these supplies during emergencies, using stockpiling and other reserve build-up measures. The Service already has underway a na-

ders, were gathered together in 1955 into a group now known as the ECHO viruses. The first adenoviruses were reported toward the end of 1953 and early 1954 by Rowe and his co-workers and by Hilleman and his co-workers. The Sendai virus, or the hemagglutinating virus of Japan, recently named influenza D, was first reported by Kuroya and associates in 1953. Other new myxoviruses, the croup-associated (CA) virus, the hemadsorption viruses (HA), the respiratory syncytial virus, or chimpanzee coryza agent (CCA), the salivary gland virus (SGV), and JH and 2060 viruses, have all been reported since 1955 by Chanock, Smith, Rowe, Weller, Price, Pelon, Mogabgab, and their co-workers. The HA viruses were reported by our laboratory only this year.

Clinical Illnesses

Fifteen clinically and epidemiologically distinguishable entities attributable to the newly recognized viruses are listed in the tabulations that follow. When the more specific signs and symptoms are not produced, the illnesses are generally lumped under such nonspecific terms as "common cold," "virus infection," "fever of undetermined origin," and "acute respiratory illness." In the warm months they might be called "summer grippé"; in the cold months "febrile colds."

Enteroviruses

Five clinically distinct entities, namely, herpangina, epidemic pleurodynia, aseptic meningitis, epidemic exanthemata, and myocarditis neonatorum, now well established as Coxsackie and ECHO viral diseases, are listed below together with acute summer respiratory illnesses.

Disease	Viral serotypes incriminated, 1958
Herpangina (vesicular pharyngitis)-----	Coxsackie group A 2, 4, 5, 6, 8, 10 (probably 3)
Epidemic pleurodynia (Bornholm disease)-----	Coxsackie group B 1, 2, 3, 4, 5
Aseptic meningitis (nonbacterial meningitis) ¹ -----	Coxsackie group A 7, 9; group B 1, 2, 3, 4, 5; ECHO 4, 6, 9, (14)

Epidemic exanthemata ("Boston exanthem") ("meningoencephalitis with rash")---	ECHO 9, 10
Myocarditis neonatorum (acute aseptic myocarditis)---	Coxsackie group B 3, 4
Acute febrile respiratory illnesses ("summer grippé") ¹	Many of the new viruses.

¹ These diseases are caused also by other enteroviruses including polioviruses types 1, 2, and 3.

Not only can certain virus types cause different clinical illnesses, but it is also apparent that the same clinical illness, such as aseptic meningitis, can be caused by a number of distinct virus types. Double and even triple simultaneous virus infections add to the complexity of the clinical aspects of these viruses.

Adenoviruses

At least six distinct entities are currently attributable to adenovirus infections. They are the following:

Disease	Adenovirus types implicated	
	Most commonly	Less commonly
Acute respiratory disease-----	4, 7	3, 14
Pharyngoconjunctival fever---	3, 7a	1, 2, 5, 6, 14
Acute febrile pharyngitis-----	1, 2, 3, 5	
Follicular conjunctivitis-----	3, 7a	2, 6, 9, 10
Epidemic keratoconjunctivitis--	1 8	2 3, 2 7a
Virus pneumonia:		
Infants-----	7a	1, 3
Adults-----	4, 7	3

¹ Classic cases.
² Mild cases.

The first clinical illness shown to be caused by adenoviruses was acute respiratory disease (ARD). This common epidemic disease of military recruits is caused most frequently by types 4 and 7. These serotypes rarely occur in children in the United States. Most adults eventually develop antibodies to types 4 and 7.

Pharyngoconjunctival fever (PCF) occurs in children in any month. It is frequently associated with swimming pools and camps. Attributed chiefly to serotypes 3 and 7a, it occurs only sporadically in adults. Many if not most adults have antibodies to these serotypes.

The most common manifestation of adenoviruses is acute febrile pharyngitis due to types 1, 2, 3, and 5 in infants and young children.

70 Newly Recognized Viruses in Man

ROBERT J. HUEBNER, M.D.

THE 1948 textbook, *Virus and Rickettsial Diseases of Man* (Rivers), listed approximately 60 viruses which were known to infect man. Two-thirds of these agents were animal or arthropod agents which involve man only secondarily. Truly human viruses (that is, parasites specific for man and dependent on him for maintenance of their parasitic cycle) recognized in 1948 numbered a mere 20, of which only 9 were established in the laboratory. Ten years later, in 1958, 70 additional, specifically human viruses have been established and studied in the laboratory.

The newly recognized agents are not only numerous but exceedingly prevalent, and in intensely populated urban areas it appears that most humans at one time or another experience most of them. Unlike the viral diseases of man transmitted from other species, these common viruses tend to be milder in their pathogenic activity and only very rarely fatal. This mildness is not unexpected, since they are dependent on man, their natural host, for the perpetuation

of their parasitic existence. Many animal and arthropod viruses which quickly lay the human low produce extremely mild effects in their natural hosts.

The following is the current box score of newly recognized viruses (1958), including polioviruses. For purposes of discussion, the viruses are divided into the enteroviruses and the respiratory tract viruses. This is an arbitrary separation, based on the sites in which the viruses are commonly demonstrated. However, most of the enteroviruses can and do occur in the pharynx, at least during the brief, early stages of infection. Similarly, some of the respiratory tract viruses, particularly the adenoviruses, can be demonstrated in the intestinal tract. One might consider as newly recognized the newer influenzal strains of type A and type B. Influenza C, measles, chickenpox, and herpes zoster have only recently been established in laboratory systems.

Enteroviruses

Coxsackie :	Number
Group A-----	19
Group B-----	5
ECHO-----	20

Respiratory tract viruses

Adenoviruses-----	18
New myxoviruses (Sendai, group associated, hemadsorption, types 1 and 2)-----	4
Other viruses (salivary gland virus, JH, 2060, respiratory syncytial)-----	4

70

Dr. Huebner is chief of the Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases of the Public Health Service. This article is a condensation of a paper presented for the Institute of Microbiology, Rutgers University, in a symposium sponsored by Gustav Stern, president of Hartz Mountain Products, in honor of the late Dr. F. R. Beaudette, who was chairman of the department of animal pathology, Rutgers University College of Agriculture. It is printed with permission of Rutgers and John Wiley and Sons, Inc., publisher of the book in which the full version of the paper will appear, Perspectives in Virology, edited by Morris Pollard. Publication of the book is scheduled for next month.

The first representatives of the Coxsackie viruses were reported by Dalldorf and Sickles in 1948. Subsequently, agents isolated in tissue culture, called orphan viruses by Melnick, and enteric viruses by Sabin, Hammond, and En-

Pneumonitis in infants and children -----	Sendai (Influenza D), CCA, IIA type 1
Mild respiratory illness (common cold, coryza, nasopharyngitis) -----	JH, 2060, CCA
Acute febrile respiratory illnesses -----	Sendai, CA, IIA types 1 and 2
Cytomegalic inclusion disease. -----	Salivary gland virus

Chanock and associates showed a temporal association of the new respiratory syncytial virus with such pneumonitis in infants and children. This virus was shown to be identical with the chimpanzee coryza agent (CCA) reported earlier by Morris and associates. This virus, like the croup-associated virus, appears to occur in sharply localized epidemics.

Two viruses with similar properties, JH virus and 2060 virus, were reported almost simultaneously from two separate laboratories, in association with mild respiratory illnesses with very low-grade fever. Subsequently, Price has reported protection against an outbreak of mild respiratory disease in children with a vaccine prepared against the JH strain.

The virus causing cytomegalic inclusion disease, so termed because of the distinctive giant intranuclear inclusions produced, is, in a sense, an old virus in that it was recognized as a pathological entity many years ago. This virus, however, was not isolated and established in the laboratory until 1956, when Smith reported its recovery in human uterine fibroblasts. Shortly afterwards, Rowe, Hartley, and I, as well as Weller, reported in some detail on the occurrence of this virus in man. It would appear that the salivary gland virus, as it is also known, is an extremely common and ubiquitous agent in man. Related but species-specific representatives occur in many other mammals. The mouse and guinea pig varieties have also been established in tissue culture.

This group of viruses occasionally causes disseminated disease with lesions observed in nearly all the critical organs in the species in which they occur. The human agent in its active form in newborn infants, called cytomegalic inclusion disease, is frequently fatal. Weller and Rowe recently showed that the virus can be demonstrated for long periods in salivary secretions and in urine of infected children.

Like adenoviruses, the human agent has been unmasked from long-term cultures of tonsils and adenoids.

The search for human viruses has demonstrated previously unrecognized viruses in other species as well. At least 20 newly recognized viruses have been demonstrated in tissue cultures of monkey kidneys. Some are biologically and immunologically related to human adenoviruses, others to human ECHO viruses, and others to the newer hemadsorption myxoviruses.

Implications

Recognition of so many new viruses and their effects cannot fail to provoke a reexamination of current concepts. It is a familiar observation that the usefulness of hypotheses concerning the etiology of disease depend in great part upon whether or not they can be tested. When they are based on a microbial theory, this necessary and desirable circumstance usually obtains. But such testing is not always easily accomplished.

One of the most important implications of so many new, different, and prevalent viruses is the complexity of the business of trying to find out what they are doing in their hosts. Simultaneous infections with multiple viruses are commonplace, particularly in young infants. We have observed as many as four acute viral infections in the same child during the same week. Since, in very young children, these new viruses most often cause clinical entities that are difficult to distinguish from one another, attributing the illness to the proper agent can be quite difficult. The elucidation of significant etiological associations of prevalent viruses which only rarely cause fatal infections becomes, as a consequence, almost a problem in logistics, requiring carefully planned, extensive, and controlled epidemiological and laboratory studies. One of the more proximate and important implications of modern research on virus diseases, therefore, is that it will cost significantly more money than microbiological studies have in the past.

Clinical Importance of New Viruses

Specific clinical illnesses attributable to viruses may represent only a small proportion

Most are infected with types 1 and 2, it would appear, prior to entering grade school. These febrile illnesses are much more common in cold seasons. They are quite similar to pharyngoconjunctival fever, except that conjunctival inflammation is rare. Common follicular conjunctivitis without fever, due to adenoviruses, is seldom epidemic. It is observed most often in adults, since in children adenoviruses tend to produce fever; in which case the illness would more properly be called pharyngoconjunctival fever.

Epidemic keratoconjunctivitis (EKC) appears to be most commonly caused by type 8 adenovirus. It occurred chiefly in industrial areas during World War II. EKC is prevalent in Japan and has recently been observed in Scotland and in continental Europe. When type 8 infections are observed in children, as in Japan, the illness tends to resemble pharyngoconjunctival fever; in adults, the infection usually results in classic afebrile keratoconjunctivitis.

Other adenoviruses (types 3 and 7a) can also on occasion cause mild keratitis expressed as subepithelial opacities which, according to Thygeson, are distinguishable from the severe and prolonged classic EKC, which not infrequently is followed by permanent corneal damage.

Primary atypical pneumonia without cold agglutinins was found associated with adenovirus infections, chiefly type 4, by Hilleman and Werner. This illness is invariably associated with outbreaks of ARD. Virus pneumonia in infancy is the most recent illness shown to be caused by adenoviruses. Type 7a was demonstrated repeatedly during an epidemic of virus pneumonia in infants in Paris, 1955-56. The findings in fatal cases resembled very closely an unusual pneumonia described by Goodpasture in 1938, which featured intranuclear inclusions quite similar to those produced by adenoviruses in cells grown in tissue culture. Types 1 and 3 have also been found in the tissues of infants dying from pneumonia in this country.

As illustrated in the tabulation, certain adenoviruses can also cause clinically different illnesses, and the same illness may have multiple adenovirus causes.

Myxoviruses

The myxoviruses, particularly influenza, mumps, and Newcastle, are probably the most intensively studied of the animal viruses. In recent years, however, new human myxoviruses have been found, with properties differentiating them from the older varieties. In 1955, outbreaks of infant pneumonitis were associated with a new myxovirus called Sendai virus, isolated so far, only in Sendai, Japan, and in Vladivostok, Russia. However, serologic reactions to Sendai virus in this country, England, and elsewhere, suggest that Sendai virus or an immunologically related virus was causing prevalent infections.

In 1954, Chanock reported a croup-associated virus. When propagated in monkey kidney tissue culture, CA virus revealed minor serologic relationships to mumps and to Sendai virus. The hemadsorption myxoviruses types 1 and 2, discovered not many months ago by Chanock and others of my associates at the National Institutes of Health, in collaboration with Dr. Robert Parrott, physician-in-chief, Children's Hospital, Washington, D. C., are also isolated in monkey kidney tissue cultures, but they require the new hemadsorption technique, described by Vogel and Shelokov, for their demonstration. These agents appear to be responsible for a significant amount of acute febrile respiratory illness in children in urban areas.

Our recent hospital clinic studies, done in collaboration with Children's Hospital, Washington, D. C., and the District of Columbia Welfare Department, indicate that types 1 and 2 hemadsorption viruses were responsible for as much as 25 percent of the influenza-like illnesses observed during recent months in children. Retrospective studies indicate that the hemadsorption viruses may have been responsible for a relatively high proportion of respiratory illnesses in children, at least since 1953, and may have caused in military recruits a proportion of acute respiratory disease not accounted for by the streptococci, influenza virus, or the adenoviruses. The following shows the illnesses associated with newly recognized myxoviruses and other respiratory tract diseases:

Acute laryngo-tracheobronchitis (croup)----- CA, HA type 2

At the National Institutes of Health, we are engaged in preliminary tests of properly constituted viral vaccines. Our studies of the high prevalence of viral illnesses in children suggest that a properly constituted, safe, and effective vaccine would probably be incorporated in pediatric immunization schedules. Such a vaccine would require perhaps as many as 25 separate viral antigens.

Speculation concerning the eventual utilization of this hypothetical "virus cocktail" is premature. Too many questions remain to be answered. Some may feel that such a vaccine would be fraught with unexpected hazards either immediately or later in life. Others may assume that such a vaccine would be of immediate great value. Generally speaking, the first vaccines for any disease are poorer than the modifications that come later. However, it is important to take the initial steps, carefully, of course, and then to answer questions as they become real rather than merely hypothetical.

The justification for study and eventual use of an all-purpose virus vaccine ought not to be put purely on an economic basis. I believe that a multivalent vaccine capable of preventing as much as 25-30 percent of undifferentiated respiratory disease, particularly in early childhood, would be desirable for the good and simple reason that this is, in any vocabulary, an enormous mass of illness, probably much more illness than is now prevented by all currently available vaccines.

New Viruses and Noninfectious Disease

It has been only a few years since our chief infectious diseases were pneumonia, smallpox, diphtheria, and the great plagues, the latter mostly transmitted from other animal species to man. Although vigilance is still required to keep them in check, they are no longer regarded as important, at least in this country.

This remarkable success story has led to an unfortunate myth that infectious disease research is now a comparatively dead science. Nevertheless, numerically speaking, it would appear that most of Western man's microbial experiences, as exemplified in large part by the newly recognized virus flora, still remain to be defined, if not eliminated.

Many chronic and degenerative diseases also

remain largely a riddle as to ultimate causes. Among the various hypotheses, those which postulate viral etiology deserve consideration. As viral infections are most frequent precisely during the formative periods, they frequently affect organs that are critically necessary for healthy growth. Despite the fact that the newly recognized and numerous human viruses are almost never fatal, the astronomic number of illnesses they cause seems to me to imply a great deal. Our knowledge of the pathogenic behavior of these viruses rests on comparatively few autopsies. But from studies of these few fatal cases, it is quite clear that many representatives of the new and common viruses cause pathology in critical organs, including the central nervous system, lungs, heart, liver, adrenals, kidneys, and the reticuloendothelial system. It is almost impossible to think that these pathological effects are not duplicated, to a lesser extent, in many nonfatal infections.

The well-known virus diseases of early childhood, measles, mumps, chickenpox, herpes, and poliomyelitis, also cause pathology in central organs with uncomfortable frequency. No fewer than 14 Cocksackie and ECHO viruses have now been shown to affect the central nervous system. Certain enteroviruses also cause myocarditis and pericarditis in children. It is quite possible that repeated infections in childhood with specifically human viruses which affect the central nervous system represent far greater contemporary threats to human health than all the viral encephalitides transmitted from nature combined.

Consider also the salivary gland virus, a notorious cause of neonatal death, and, as recently demonstrated by Weller and Rowe, a potential cause of chronic cerebral disease in infants who survive the early perinatal infection. In fatal cases, this virus causes lesions in virtually all the critical organs; it has been shown to be excreted by as many as 10 percent of infants under the age of 3; and serologic surveys show that it eventually succeeds in producing infectious processes in perhaps as many as 80 percent of all persons by the time they reach 35 or 40. Furthermore, the infection is persistent and has been reported occasionally as a generalized recrudescence disease in fatal illnesses, usually attributed to other chronic maladies. It is un-

of the total amount of illness they produce. Our studies, as well as those of Dingle's group at Western Reserve University and the Newcastle-on-Tyne studies in England, show that the common respiratory and other undifferentiated illnesses tend to occur most frequently in the young child. In this age group, it is difficult even for a pediatrician to distinguish among the illnesses most commonly caused by the adenoviruses, Coxsackie, ECHO, and even polioviruses.

The 6-year longitudinal study of suburban communities, by Bell and my other associates at the National Institutes of Health, showed that respiratory illnesses characterized by mild fever of more than 1 day's duration occurred approximately 5 times more often in children under 6 years of age than in persons over 17. The intermediate age group showed an intermediate experience. For this reason, our recent studies of these illnesses have been focused on the childhood illnesses in three different population groups: (a) in the suburban community, (b) in pediatric hospital wards and clinics, and (c) in infants and young children confined to an orphanage nursery. By longitudinal and cross-sectional observations, we hope to determine more precisely the roles of viruses, and other pathogens as well, in producing the common acute and undifferentiated illnesses in children.

Already these studies have led to interesting findings. For instance, in collaboration with Dr. Robert Parrott, our group is now engaged in studying the relative contributions of Asian influenza, the brand-new hemadsorption viruses, and the adenoviruses to current pediatric respiratory illnesses in local pediatric clinics and hospital wards. During October and November 1957, approximately 60 percent of the acute respiratory illnesses could be attributed to Asian influenza and approximately 25 percent to types 1 and 2 hemadsorption viruses. The adenoviruses, the croup-associated virus, the respiratory syncytial virus, as well as Coxsackie and ECHO viruses, known to be prevalent at other times and places, were not prevalent during this period. Because of technical difficulties, we have been unable thus far to assay the contributions of JH and 2060 viruses.

During October and November, we were able to account for the majority of the respiratory illnesses on the basis of Asian influenza and the new hemadsorption viruses. In December 1957, when the Asian influenza virus disappeared entirely from the clinic and hospital wards, approximately 25 percent of respiratory illnesses could still be attributed to the hemadsorption viruses. The adenoviruses appeared in December and were held responsible for approximately 5 percent. Of the respiratory illnesses observed for about 60 days, these two agents produced 30 percent.

Asian influenza reappeared in February, but only a small percentage of illnesses were attributable to this virus. In late February, type 1 hemadsorption virus disappeared. At this time, we were able to account for probably less than 15 percent of the acute respiratory and undifferentiated illnesses. Subsequently the hemadsorption virus reappeared and adenoviruses became more common, but large segments of respiratory disease remained unexplained. Since bacteriological studies have provided no explanation for the vast majority of unexplained illnesses, additional, presumably new, viruses will have to be sought.

Longitudinal studies in an orphanage nursery have provided us with observations on thousands of respiratory and undifferentiated illnesses. Thousands of virus isolates were obtained and, for the most part, identified. (The data are being prepared for publication.) At least 35 to 40 different prevalent viruses occur regularly in this population, and substantial amounts of illnesses can be attributed to the adenoviruses, some of the enteroviruses, and myxoviruses. During nearly 3 years of observation since 1955, many of these viruses have made periodic, almost predictable, reappearances at appropriate seasons. However, even under intensive scrutiny, many illnesses still cannot be identified as viral or bacterial infections.

Prophylactic Vaccines

Even though there are still many common respiratory and other undifferentiated diseases with no known agent, serious consideration should be given to the development of prophylactic viral vaccines.

Local Health Departments

GROWTH or ILLUSION?

BARKEV S. SANDERS, Ph.D.

STUDENTS of public health as well as civic leaders have begun to scrutinize the efficacy of the traditional pattern of local health departments (1-3). A critical look at the growth of these departments in recent years is therefore timely.

The growth of local health departments may be measured in several ways, each way possibly leading to a different conclusion. When independent approaches lead to common conclusions, however, we are justified in having greater confidence in the findings. We have chosen three methods of measuring the growth of local health departments in recent years:

- Extent of geographic areas covered by local health departments.
- Annual expenditures of local health departments.
- Number and skills of full-time local public health personnel.

Geographic Coverage

A few large cities in Europe and in the United States had developed municipal health departments even before the 19th century, but the

Dr. Sanders is technical consultant, Program Development Branch, Division of General Health Services, Public Health Service. The article is based on a speech given at the annual conference of the Nebraska State Public Health Association in Lincoln, September 23, 1957. Basic data on the areas, expenditures, and personnel were compiled under the direction of Clifford H. Greve, State Grants Branch, Division of General Health Services.

countywide local health department in this country is exclusively the product of the 20th century. According to Williams (4): "There are conflicting claims as to where the first full-time county health department was established. The records indicate that Jefferson County, in which the City of Louisville, Kentucky, is situated, established a full-time health department in 1908. In Guilford, North Carolina, a full-time county health department was established in 1911."

In 1915 there were 15 full-time county health departments; by 1930 this number had risen to 534 (5). Since these early beginnings, both the number of separate health units and the number of counties with such health units have vastly increased.

The period of greatest growth of full-time local health organizations was between the years 1915 and 1940 (table 1). Since 1950 there have been relatively few additions. The yearly number of counties with organized health departments and the percentage of population included in areas with such departments underscore this conclusion.

Although the rate of expansion in area and in population covered since 1950 has been negligible, this need not mean that local health departments have not grown in other respects: in quality and in scope of services. We, therefore, should look at other indexes of growth.

Annual Expenditures

From 1947 to 1956, expenditures through local health departments rose almost constantly. Al-

reasonable to think that the giant intranuclear inclusions produced by the generalized disease are confined to fatal cases. This and other latent viruses may have outstanding importance for those suffering from a lack of testable hypotheses concerning ultimate causes in certain chronic diseases.

Viruses in Etiology of Human Cancer

It has become clear that the viruses responsible for animal tumors are not altogether strange microbes. Recent studies have shown that the animal tumor viruses grow to high titer, that they produce antibodies, and that some of them grow in tissue cultures. Their manifestations are generally hyperplastic rather than cytolytic and the viruses frequently remain latent for many months; but these are not unusual properties. Only their oncogenic activities set them apart. The methods for working with them appear to be slightly more difficult than those for some of the ordinary, non-tumor viruses, yet they seem to present no more severe technical problems than, for example, the salivary gland viruses.

The delineation of certain viruses in one species has frequently been based upon studies of similar viral experiences in other species. When representatives of various families of human viruses turn up in animal species other than man, it is merely taken for granted. In the same way, it is not uncommon for the first representatives of a virus family to be found in an animal species, then, subsequently, related representatives to be found in man. It is hardly possible for a virologist to think that family relatives of the numerous tumor viruses of animals will find no expression in the human species. To say that such a virus has never been demonstrated is quite correct. It is equally correct to say, however, that the critical experiments which have been necessary for the demonstration of animal cancer agents in man have not yet been performed. In fact, the question "Do viruses cause human cancer?" has not yet been effectively asked. One of the major implications of modern virus research, therefore, is based on the likelihood of an early answer to this most important medical question.

Regular Corps Examinations

The Public Health Service announces competitive examinations for appointment of physicians, dentists, sanitary engineers, clinical psychologists, biochemists, and veterinarians to its commissioned corps as Regular Corps officers.

The examinations will be held throughout the country on March 31 to April 3, 1959, for the veterinarians and on April 21-24, 1959, for the other categories.

Appointments will be made in the ranks of assistant and senior assistant grades, equivalent to Navy ranks of lieutenant (j.g.) and lieutenant, respectively. Active duty as a Public Health Service officer fulfills the obligations of Selective Service.

Only United States citizens need apply and applicants must be at least 21 years old. The entrance pay is \$4,817 per year for an assistant grade officer with dependents and \$6,270 for a senior assistant grade officer with dependents. Physicians, dentists, and veterinarians receive an extra \$1,200 to \$3,000 a year incentive pay.

Applications for the veterinarian's examination must be received by the Surgeon General no later than February 20, and March 6 for the other categories. Forms may be obtained by writing to the Surgeon General, Public Health Service (P), Washington 25, D. C., or to the nearest field station of the Service.

Table 2. Annual expenditures by local health departments, by source of funds, 1947-56

Fiscal year	Total expenditures	Local	State	Federal	Private agencies
1947.....	\$70,876,248	\$53,754,050	\$10,270,597	\$15,180,501	\$671,100

¹ Three-fourths of increase between 1950 and 1951 attributed to four States: New York, Michigan, Ohio, and Pennsylvania. Increased expenditure was sizable in some of the large cities in the first three States, and more complete reporting of expenditures was noted for Pennsylvania. Some increase was shown, however, for most States.

² Although increases between 1951 and 1952 were reported by many States, sizable reduction in funds expended was reported for Detroit and for New York City. The decrease in Detroit resulted from the elimination of general hospitalization cost. Apparently, reported expenditures were incomplete for New York City for 1952.

³ Federal poliomyelitis funds eliminated for reasons of comparability.

tained by applying these two indexes to the actual expenditures given in table 2. The top part of table 3 shows what the annual amounts would be after having been deflated by the Consumer Price Index; the lower part, the amounts after further adjustments to allow for population increases.

Both sets of figures are smaller, of course, than those based on current dollars in table 2. The total, deflated by applying the Consumer Price Index only, shows a 30 percent increase instead of the 47 percent increase in table 2. In terms of deflated dollars the increase in local funds was 35 percent instead of 52 percent and in State funds 52 percent instead of 72 percent. Expenditures of Federal funds by local health departments declined 39 percent in deflated dollars compared with 31 percent in terms of current dollars.

As would be expected, adjustments for population increases reduce the expenditure figures even more. The deflated dollars in table 3 show increases of 14 percent for total expenditures, 19 percent for expenditures of local funds, and 34 percent for expenditures of State funds, and a decrease of 47 percent in expenditures of Federal money.

Although deflation by the Consumer Price Index reduces the slope of the increase in expenditures, the slope still shows some increase.

The question arises whether this index adequately equates the purchasing power of dollars spent for public health. The Consumer Price Index will reduce dollars expended to a common base only if the items purchased are the same commodities and in the same proportions on which the index was based or are closely correlated with these. We know that few local health department dollars are spent for food, clothing, and housing, items which constitute almost three-fourths of all expenditures in the Consumer Price Index. It follows therefore that the use of this index to equate the purchasing power of local health department dollars may not be appropriate. In spite of the deflated amounts obtained by the application of the index, we may still be comparing dollars of unequal purchasing power in different years for the kind of things that were purchased by local health departments.

Deflating Expenditures by Wage Index

The bulk of local health department expenditures is for personnel. Emerson found that in 1942 the total expenditures of local health departments were \$77.3 million, of which \$62.7 million, or 81 percent, was spent for salaries (6). There is no ready-made index as to what adjustments should be made in dollar values

though there was some slackening in the rate of increase, the year-to-year changes in total expenditures were generally upward (table 2).

From 1950 to 1956 total expenditures increased 47 percent, averaging about 8 percent per year. Local funds, which constituted two-thirds of the total, increased 52 percent, closely paralleling the increase in total expenditures. Although fewer dollars are involved, the percentage rise in State funds expended by local health departments (72 percent, or about 12 percent a year) was significantly greater than either the total or local increases.

Within this same period, there was a marked decline (31 percent) in the Federal portion. In 1947 Federal funds represented 19 percent of all local public health expenditures; by 1956 this percentage had dropped to 5.

The casual observer, noting the rise in dollar amounts spent for health programs, may assume that community health needs are being taken care of more adequately today, at least

in the areas served by full-time health departments. This presumption is subject to question, however, since the increases occurred in a period of rising costs, when the purchasing power of the dollar was steadily declining.

Equating the Value of the Dollar

Ordinarily, the economist uses the Consumer Price Index of the Bureau of Labor Statistics in order to convert current dollars into uniform dollars. For most purposes this provides a reasonably adequate adjustment.

The Consumer Price Index uses as its base the prices paid for consumer goods and services purchased by wage earners' families in the period 1947-49. Appraisal of the significance of increases in dollar amounts should also include an adjustment for the population increase in counties served by local health departments in terms of an index reflecting this increase.

The expenditure figures in table 3 were ob-

⁴ The difference between 1949 and 1950 is due partly to adjustments made possible by current population figures for 1950 provided by the 1950 census.

⁵ Estimated.

Figure 1. Annual expenditures by local health departments compared with expenditures deflated by wage and salary index and by population increase, 1950-56.

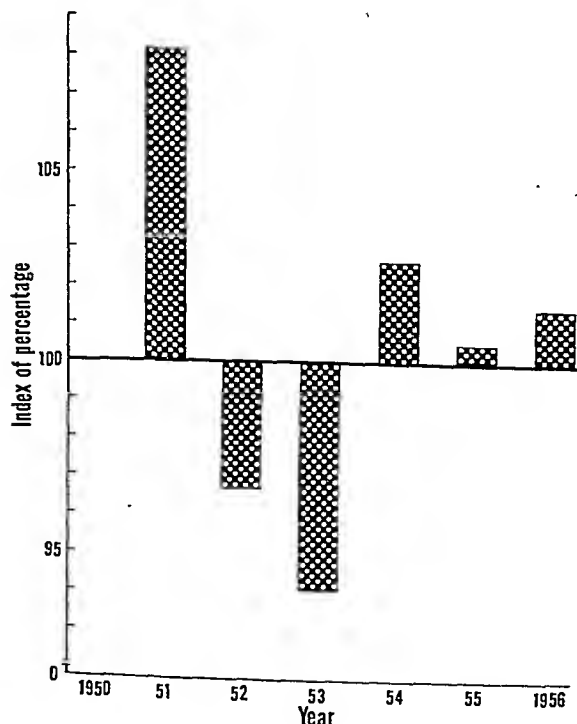

the disparity between the expenditures in 1951 and 1952 may not be real, as explained in footnote 2 of table 2. Excluding this one year, however, the maximum increase between the lowest and the highest year is only 10 percent. Local funds parallel the total closely since they constitute the largest component. The State funds follow an even less consistent pattern of growth, the highest expenditure occurring in 1954. Federal funds declined progressively until by 1956 they were about half of the amount available in 1950.

The figures in the lower part of table 4, if one considers the population increase in counties with organized health departments in addition to adjusted dollar values, indicate an actual decline in "real" expenditures between 1950 and 1956. The effect of these two adjustments is depicted also in figure 1.

Percentage of Gross National Product

The relative growth or decline of interest in a public endeavor can be appraised by the por-

to give uniform purchasing power for the types of expenditures for which local health department dollars are used. Since well over 80 percent of these expenditures are for wages and salaries of employees, an index based on wages of public health workers for the different years would largely meet the need. However, up-to-date information for such an index is not readily available. The latest publication giving information of this type was for 1953 (7). A more readily available measure—more conservative and yet not too far removed from the appropriate index—would be one based on the annual earnings of full-time equivalent workers (8). The index derived, with 1947-49

as the base, is as follows: 110, 118, 125, 131, 134, 140, and 147, for the years 1950 through 1956, respectively.

Table 4 first shows local health department expenditures equated in terms of wages paid in different years to equivalent full-time workers. The figures in the lower half of the table result from an additional adjustment for population increases in counties with full-time health departments.

Total expenditures by local health departments have increased very little in terms of uniform wage dollars. The highest expenditure was for 1951, primarily due, as indicated by

Table 4. Annual expenditures by local health departments by source of funds, deflated by a wage and salary index¹ and by the population index,² 1950-56

SOURCE: U. S. Office of Business Economics, Survey of Current Business (National Income Number) 37: 20 (table 27), July 1957, for 1952 through 1956. For earlier years, data were obtained from: U. S. Office of Business Economics, National Income, 1954 Edition, A Supplement to the Survey of Current Business.

the Nation. This differential increase between 1950 and 1956 was about 3 percent. If the indexes in table 5 were adjusted accordingly, it would indicate that the per capita share of gross national product spent by local public health departments declined slightly between 1950 and 1956.

The general inference that we draw is this: Since 1950 there has been no upward trend in real expenditures by public health departments, and, if the increase of population is taken into consideration, there has been perhaps a slight decline. The decline, nevertheless, may be poignant because it occurred in years of unrivaled economic prosperity and in years when particular segments of our population, children and the aged, who stand to gain most from organized public health efforts, were increasing at an appreciably higher rate than the population at large.

We may examine now, by way of a check, the number and kinds of personnel serving local health departments.

Personnel in Local Health Departments

The *raison d'être* of local health departments is to supply directly or otherwise specified health services needed by individuals, families, and the community. The nature and volume of these services may be judged from the number and kinds of personnel employed. Table 6 provides data on full-time personnel for the period 1949 through 1957. Data are not available on the number of part-time personnel employed by local health departments nor on the extent to which these workers have increased or decreased since 1950.

The overall increase of local health department personnel between 1949 and 1957 is 5,394, which is 16 percent, or about 2 percent per year on an average. Since the increase in population in areas served by local health departments during this period has been about the same, one can assume that there has been no per capita increase of service personnel.

An actual decline has occurred in certain types of key personnel in local health departments. Declines in the number of physicians between 1949 and 1957 are observed even without considering the population increase.

Actual declines are observed also in the number of laboratory personnel. Most of the other positions show net gains that are reversed when full-time personnel positions are related to the population increases. One marked exception to this is the small but sharply growing group of medical and psychiatric social workers who more than doubled in number during the interval between 1949 and 1957. The dentists are a second exception. This group is small, but showed an increase of 31 percent between 1949 and 1957.

Summary and Conclusion

Analysis of three criteria of growth, geographic expansion, annual expenditures, and number of full-time health department employees, leads to the conclusion that there has been no growth in local health departments since 1950. In fact, if the population increase in the areas with local health departments is taken into consideration, there is indication of a small decline. This could mean that other agencies are taking over certain needed health services, or that American communities are not so much interested in health, or perhaps health needs that can be dealt with effectively by local health departments have diminished.

Further research is needed to ascertain which of these factors, or in what combinations these or perhaps still other factors, may account for the apparent lack of growth in local health departments. Even more fundamental research is required into methods of reexamining our objectives and determining priorities for local health departments to keep in tune with the times in a rapidly changing society. Also, more precise and objective methods of measuring accomplishment need to be devised in order to learn how best to apportion available funds for local health services in different communities with varying needs and resources.

- (3) U. S. Public Health Service: The development of community health services. Material prepared

tion of resources that the community diverts to the activity. To obtain such a measure, the monies spent each year by local health departments may be related to the gross national product.

The gross national product is the measurement in terms of current dollar values of all the goods and services produced by the Nation in a given year. What proportion of this total is allocated to public health services provided by local health departments? More specifically, has this proportion increased, decreased, or remained more or less stationary during the years 1950 through 1956?

These relationships are shown in table 5. Expenditures by local health departments between 1950 and 1956 were less than one-half of 1 percent of the gross national product.

The largest increase occurred in 1951, but this apparent increase has already been somewhat discounted. Other year-to-year variations are well within the estimation errors present in all these data (table 5 and fig. 2). Ignoring the sharp increase in 1951, one is led to conclude that since 1950 there has been no significant increase in expenditures by local health departments.

In considering percentage of gross national product, we need no special adjustment for the increase in population since the gross national product already reflects population changes. Nevertheless, there might be need for additional adjustment for population in terms of the differential increase of the population in areas with full-time health departments compared with the increase of the population for

A 1-month study in an urban-rural Tennessee county shows that non-hospitalized patients with diseases of the heart and blood vessels receive many nursing services which are specifically related to their diagnoses and significant to their welfare.

Nursing Services Outside the Hospital for Cardiovascular Disease Patients

MARGARET DENHAM, SIDNEY ABRAHAM, and L. M. GRAVES, M.D.

MORE PEOPLE in the United States are affected, directly and indirectly, by cardiovascular diseases than by any other type of illness. Each year more than half of all deaths in this country are caused by diseases of the heart and blood vessels.

Currently, no valid nationwide statistics on the prevalence of these diseases are available. It is logical to assume, however, that persons with cardiovascular disease comprise the largest single group of patients outside the hospital in need of nursing service. Many physicians, health administrators, and nurses have long been concerned with identifying specifically the elements of public health nursing care being provided to such patients.

A project to effect this identification was carried out during October 1956, when services by 71 nurses to 385 patients with cardiovascular disease outside of hospitals in Shelby County, Tenn., were studied. This area was selected when Memphis nursing groups, while planning an educational program, analyzed their own ac-

tivities and discovered that the nursing staff of the Memphis and Shelby County Health Department for several years had consistently reported about 1,000 visits a month to individuals with a diagnosis of cardiac disease. The small staff of the Visiting Nurse Association of Memphis also reported a high proportion of service to cardiovascular disease patients.

Interest in examining the nursing service comprising this sizable volume was evinced by the medical and nursing directors of the city-county health department, and by the director of the visiting nurse association. Subsequently, detailed plans for the survey were formulated in cooperation with the Heart Disease Control Program, Public Health Service.

The month of October, considered to be typical, was chosen for the collection of data, since this was normally a period in which the least interruption of the usual activities in both local agencies was expected. Data were collected by the nurses as part of their usual duties. No changes in their regular recording procedures were made except that a temporary form for use during the study month was substituted for the permanent record.

Through mutual agreement all the visits to patients with cardiovascular disease during the month were studied to determine the nursing services given to them.

Miss Denham is chief nursing consultant and Mr. Abraham is statistician with the Heart Disease Control Program, Division of Special Health Services, Public Health Service. Dr. Graves is director of the Memphis and Shelby County Health Department, Memphis, Tenn.

Medical Education Group Formed

The Surgeon General's Consultant Group on Medical Education, composed of 21 members, held its first meeting in Washington, D. C., December 8, 1958, with Frank Bane, former executive secretary of the Council of State Governments, as chairman.

The members of the group, national leaders in medicine, education, and public affairs, were invited by Dr. Leroy E. Burney, Surgeon General of the Public Health Service, to seek answers to the question: How can the Nation be supplied with adequate numbers of well-qualified physicians over the next decade?

Dr. Burney pointed out that the present medical school output will not keep pace with the economic and population growth of the United States, and that the present ratio of 132 physicians to every 100,000 persons will be difficult to maintain. He said that twice as many interns are needed. Public health organizations are short about 10,000 physicians, and 6,000 more psychiatrists are required to fill present vacancies. Dr. Burney also said that people are visiting their doctors twice as often as they were 25 or 30 years ago and are using hospitals at a rate three times that of

1940. With half the population in 1970 expected to be under 20 and over 65 years of age, Dr. Burney observed that health needs will change, particularly with regard to chronic diseases.

Dr. Burney has suggested that the Consultant Group on Medical Education might approach the question of supplying the Nation with adequate numbers of physicians in the following manner:

1. Appraise existing data, plans, and proposals related to medical schools and the Nation's need for physicians.
2. Identify matters upon which agreement has been reached and those that require further study.
3. Recommend actions which might be taken to achieve reasonable and acceptable goals within the next 10 to 20 years.
4. Recommend any specific actions which educational institutions, foundations, industry, and local, State, and Federal governments should take in meeting these goals.
5. Recommend the proper role, if any, that the Public Health Service should play and the steps it should take.

A 1-month study in an urban-rural Tennessee county shows that non-hospitalized patients with diseases of the heart and blood vessels receive many nursing services which are specifically related to their diagnoses and significant to their welfare.

Nursing Services Outside the Hospital for Cardiovascular Disease Patients

MARGARET DENHAM, SIDNEY ABRAHAM, and L. M. GRAVES, M.D.

MORE PEOPLE in the United States are affected, directly and indirectly, by cardiovascular diseases than by any other type of illness. Each year more than half of all deaths in this country are caused by diseases of the heart and blood vessels.

Currently, no valid nationwide statistics on the prevalence of these diseases are available. It is logical to assume, however, that persons with cardiovascular disease comprise the largest single group of patients outside the hospital in need of nursing service. Many physicians, health administrators, and nurses have long been concerned with identifying specifically the elements of public health nursing care being provided to such patients.

A project to effect this identification was carried out during October 1956, when services by 71 nurses to 385 patients with cardiovascular disease outside of hospitals in Shelby County, Tenn., were studied. This area was selected when Memphis nursing groups, while planning an educational program, analyzed their own ac-

tivities and discovered that the nursing staff of the Memphis and Shelby County Health Department for several years had consistently reported about 1,000 visits a month to individuals with a diagnosis of cardiac disease. The small staff of the Visiting Nurse Association of Memphis also reported a high proportion of service to cardiovascular disease patients.

Interest in examining the nursing service comprising this sizable volume was evinced by the medical and nursing directors of the city-county health department, and by the director of the visiting nurse association. Subsequently, detailed plans for the survey were formulated in cooperation with the Heart Disease Control Program, Public Health Service.

The month of October, considered to be typical, was chosen for the collection of data, since this was normally a period in which the least interruption of the usual activities in both local agencies was expected. Data were collected by the nurses as part of their usual duties. No changes in their regular recording procedures were made except that a temporary form for use during the study month was substituted for the permanent record.

Through mutual agreement all the visits to patients with cardiovascular disease during the month were studied to determine the nursing services given to them.

Miss Denham is chief nursing consultant and Mr. Abraham is statistician with the Heart Disease Control Program, Division of Special Health Services, Public Health Service. Dr. Graves is director of the Memphis and Shelby County Health Department, Memphis, Tenn.

The Public Health Service had an additional long-range objective. Since the components of nursing service given to patients in relation to their cardiovascular disease had not been documented previously, the experience gathered in this study could be used in designing a schedule which other agencies might use in examining their own services to patients with cardiovascular disease.

The completed study shows only an analysis of the services that the nurse recorded during the study month. It shows neither what took place in prior visits nor the length of service already given the patients. No differential was made between new and old patients. Only those patients referred for nursing services were studied. Those who reached medical care originally through the efforts of the nurse were not revealed in the study. The study cannot be used as an index of the status of all patients in the community with cardiovascular disease.

The Patients

The clinic of the City of Memphis Hospitals was the source of medical care for 76.9 percent of the 385 patients. Only 8.8 percent were under private medical care. The remaining patients received medical care from other facilities of the city hospitals. The policies limiting the nursing program of the health department were responsible for the patients being chiefly beneficiaries of the city-supported medical facilities. Private physicians requesting nursing

services were either referred to the visiting nurse association or necessarily refused service other than for teaching purposes.

Approximately 75 percent of the patients lived within the city limits of Memphis, 12.7 percent were suburban residents, and 7.0 percent lived in rural areas, and the remainder resided in suburban-urban and suburban-rural fringe areas. Most of the patients, approximately 80 percent, lived with their immediate family or relatives; only 65, or 16.9 percent of those studied, lived alone.

Sixty-five patients (16.9 percent) were school age. The health department's school health program in the city and county included responsibility for the followup of children with rheumatic fever, rheumatic heart disease, and congenital heart anomalies with both their parents and their teachers. The nurses' records indicated that conferences with the teacher were held to discuss the care of two children in relation to heart disease. However, since the study was made during the second month of the school year, such conferences may have occurred with greater frequency the preceding month. Also school records, which may have indicated other nurse-teacher conferences, were not included in this study.

Of the 385 patients, 70.6 percent were past age 45 years, and 43.6 percent were past 65. Only 8.3 percent were under 5 years of age, and 15.8 percent were between 5 and 15. Approximately one-fourth of the total patients were under 15 years of age (table 1).

Cardiovascular disease other than heart.....	⁴ 24	6.2	0	0	0	0	0	0	24	43.6

¹ Includes patients with cardiovascular disease other than heart and with medical conditions associated with cardiovascular disease; also includes 16 patients with stroke.

² Also rheumatic heart disease.

³ Also congenital heart disease.

⁴ Includes 10 with acute rheumatic fever.

Table 2 shows that 38.5 percent of the patients were diagnosed as having arteriosclerotic heart disease: 24.7 percent were diagnosed as being only arteriosclerotic, 11.2 percent as arteriosclerotic and hypertensive, and 2.6 percent as having arteriosclerosis and other heart diseases. One-fifth were diagnosed as having only hypertensive heart disease; one-tenth had rheumatic heart disease; and more than one-tenth had congenital heart anomalies. Ten patients were under treatment for acute rheumatic fever. The specific heart disease had not been determined for about one-tenth.

The heart disease in 205, or 53.2 percent, was complicated by congestive heart failure. Less than one-third (117) of all the patients had other complications such as diabetes and cerebrovascular disease.

Who Made Visits

A total of 71 nurses participated in the study. Of this number 55 were professional nurses employed by the health department for general public health service. In addition, 2 professional nurses and 1 licensed practical nurse

were assigned solely to give home service to patients attending the clinic of the City of Memphis Hospitals who required parenteral diuretics. Five clinic nurses of the health department participated in the study. The visiting nurse association's staff of eight professional nurses contributed their records for analysis.

The public health nursing staff of the health department was distributed over the entire city and county. The three specialized field nurses served chiefly in the metropolitan area and the visiting nurse association's service did not extend beyond the city of Memphis.

More than half (55.6 percent) of the patients depended upon the 55 public health nurses as their one source of service. Visits were made as a part of the nurses' routine daily activities. An additional 3.3 percent of the patients visited by these nurses were also served by the 3 specialized nurses on the health department staff. A few patients went to neighborhood clinics conducted by the health department.

A total of 1,125 visits were made to cardiovascular disease patients during October 1956. The 63 health department staff nurses reported

1,009 visits, or 89.7 percent of the total, and the 8 of the visiting nurse association, 116, or 10.3 percent.

During 1956, the health department staff reported 10,779 visits to cardiovascular disease patients, 7 percent of the total visits for all purposes during that year. Of the total visits to patients with cardiovascular disease, 9.4 percent were made during the month of the study.

In 1956 the visiting nurse association made 1,234 visits to patients with cardiovascular disease, with about one-tenth of them in the month of the study. Visits to such patients amounted to 18.5 percent of the total made to all patients by the staff that year.

What the Nurse Did

Since the chief objective of this study was to determine the scope of services given the cardiovascular patient through a nursing visit, each visit was carefully analyzed.

Through pretest procedures and a review of current medical practice 46 specific possible nursing service items were identified and incorporated in the study code. Provisions for services given but not identified in the preliminary stage of the study also were made.

These specific items were grouped under the following seven broad classifications.

Observations significant to the patient's cardiovascular disease diagnosis

1. The patient's practice in following medical orders concerning medication, diet, and rest-activity regimen.

2. The presence or absence of signs and symptoms expected in congestive heart failure or of other cardiovascular diseases or of other illness.

3. The patient's temperature.

4. Any history relating to the occurrence of rheumatic fever or the presence of pregnancy.

5. Any emotional reactions of the patient or other observations which might have significance in his disease.

Health counseling in applying medical advice or prescription

1. Helping the patient maintain normal nutrition and at the same time follow a low-sodium or low-calorie diet.

2. Working with him to achieve the kind and amount of rest and the activity prescribed.

3. Encouraging him in carrying out normal activities of daily living.

4. Listening to the patient tell his fears of sudden death or other concerns related to his disease and giving him support in maintaining emotional health.

5. Explaining penicillin and sulfonamide regimens prescribed as prophylaxis for rheumatic fever susceptibles, or prior to dental extractions and other surgical traumas for the prevention of subacute bacterial endocarditis in those with rheumatic fever or congenital heart anomalies.

6. Emphasizing the need for a separate bed for persons susceptible to rheumatic fever.

7. Stressing the importance of maintaining a high level of immunizations for those with rheumatic heart disease or congenital heart anomalies.

8. Calling attention to ways of preventing upper respiratory infections.

9. Interpreting a physician's orders.

10. Encouraging the patient to continue under medical supervision.

Drugs administered or instruction given about the medication prescribed

The drugs specifically related to the treatment of cardiovascular diseases and to the prevention or treatment of their complications were identified. They were drugs which physicians commonly prescribed for patients who were referred to the public health nurses for home supervision. They included diuretics, digitalis, insulin, prophylactic penicillin, and sulfonamide drugs. Services were administering the drug or teaching the patient how to take it.

Observations of reactions to treatment

1. Watching the rhythm, quality, and rate of pulse.

2. Taking the apical pulse.

3. Measuring the blood pressure.

4. Weighing or arranging for the weighing of the patient.

5. Noting nausea or gastric disturbance, dizziness, disturbed vision, hemorrhage, condition of skin, or any other observable reaction.

Referral for medical care

Facilities to which patients were referred were specifically identified in this category as treatment and diagnostic clinics, hospitals, emergency services, private physicians, dental services, and health department clinics.

General nursing care

1. Giving or demonstrating the bed bath.
2. Giving the patient or reviewing with him and the person who takes care of him the massage and exercise prescribed.
3. Positioning the patient to prevent contractures and thrombosis or for more comfortable breathing.
4. Giving an enema.
5. Caring for a retention catheter.
6. Teaching other specific nursing procedures.
7. Arranging for care such as home supervision of the patient or arranging transportation to medical facilities or to neighborhood clinic for medication.

Referral to other special services

Specifically identified were speech therapy services, recreation visitor, home teachers, the American Heart Association's Heart of the Home classes, and social agencies.

Services Provided

The 385 patients received 7,571 services during 1,125 visits (table 3). This represents an average per patient of 19.7 services of all types

and of 2.9 visits. The average of all types of services per visit was 6.7.

Of the seven classifications, those services grouped as "observations significant to the cardiovascular disease diagnosis" ranked highest with 355, or 92.2 percent, of the patients receiving service. Services of this type averaged 6.5 per patient and 2.3 per visit. But the average number of visits ranked third with 2.8 visits per patient.

The second largest number of patients, 349, or 90.6 percent, were given services under the classification of "health counseling." The average number of visits in this group, however, ranked fourth with 2.5 visits per patient, and the average number of services per visit, 1.9, ranked third. Services per patient averaged 4.6.

A total of 249 patients (64.7 percent) were administered a drug or instructed about self-administered drugs. They received the highest average of services, 8.0 per patient, and averaged 2.2 services per visit. Slightly more than one-half (51.2) of the patients were given a subcutaneous or intramuscular injection of a diuretic by the nurse.

"Observations of reactions to treatment" were reported for approximately the same number of patients, 247, or 64.2 percent. The reactions identified for the study were of specific significance to treatment which might be prescribed for the cardiovascular diseases. Not all possible reactions were included. An average of 1.4 observations per visit were reported.

About one-fourth, 93, of the patients were re-

Table 3. Nursing services provided cardiovascular disease patients

Classification of services	Number			Average number		
	Patients	Services	Visits	Services per patient	Visits per patient	Services per visit
All types-----	385	7,571	1,125	19.7	2.9	6.7
Observations significant to the cardiovascular disease diagnosis-----	355	2,322	994	6.5	2.8	2.3
Health counseling-----	349	1,619	865	4.6	2.5	1.9
Drugs administered or instructions given-----	249	1,984	885	8.0	3.6	2.2
Observations of reactions to treatment-----	247	1,216	845	4.9	3.4	1.4
Referral for medical care-----	93	115	112	1.2	1.2	1.0
General nursing care-----	72	294	165	4.1	2.3	1.8
Referral to other special service-----	16	21	21	1.3	1.3	1.0

ferred for medical care. Of these, 3 patients were referred for emergency medical service, 4 to dental care, and 6 to private physicians. Most of the referrals, 77, were to the city hospitals' outpatient clinic; 3 were to other clinics.

Seventy-two patients (18.7 percent) were given 294 services classed as "general nursing care" during a total of 165 visits. This amounted to an average of 2.3 visits per patient and 1.8 services per visit. Each of the 72 patients received an average of 4.1 general care services.

Sixteen patients (4.1 percent) were referred to community service agencies, but these referrals required 21 visits. One patient was referred to the home teacher service of the board of education.

The fact that a single nursing visit normally was composed of multiple services to one person and that subsequent visits to the same patient might differ in content made interpreting the data difficult. Since scope of service and not quantity alone was to be measured, the specific service item with low frequency might prove to be more significant to cardiovascular disease control than some for which more activity was reported. For example, in this study two patients when visited were found to be pregnant. Since pregnancy represents a stress factor in the woman with heart disease, this observation made early and brought to the attention of the physician could mean prolonged life for the mother. Each item, therefore, maintained its identity in the final tabulations.

All but two services anticipated at the beginning of this study were identified in the patients' records. The observation of the presence or absence of hemorrhage as a reaction to treatment and the administration of penicillin prophylaxis to persons susceptible to rheumatic fever were not reported.

The service most frequently reported was observation of signs and symptoms of congestive heart failure. Slightly more than three-fourths (77.7 percent) of the 1,125 visits recorded during the study included notations regarding these signs and symptoms. In the absence of these symptoms, the nurse may have omitted them from the record.

More than half the patients were under treatment for congestive heart failure. The 10 serv-

ices most frequently given, according to the nurses' records, were related to the treatment of this complication. Diuretics were given intramuscularly or subcutaneously to 197, or 51.1 percent, of the patients. There was indication that teaching about oral and injected diuretics had taken place on visits to 213 patients for whom the medication had been prescribed. The weight of the patient was noted on 106 visits (13.5 percent) at which diuretics were administered in the home.

Oral diuretics were used by 182 patients. On 25 visits nurses noted that patients had experienced gastrointestinal disturbances, a reaction that may have been related to the digitalis or the oral diuretic the patient was taking.

The prescribed digitalis was the most frequent of the three of the services occurring most frequently. These were teaching the patient about medication, which occurred on 451 visits; the practice in taking the drug 150 times; and counting the rhythm was noted on 150 visits of the 775 times the pul.

Other observations noted were skin, cramping of the leg also noted in the patient's ment.

Questions and Further

Certain questions for other patients can be raised as a 385 patients used nursing service one month, what had happened to persons in the community with cardiovascular disease?

The prevalence of any given condition since specific data in cardiovascular disease groups are available in determining prevalence in some degree the population of deaths from cardiovascular disease in this county and Shelby County side of the hospital patients in this disease

What needs for nursing service for those with cardiovascular disease were not filled by the two established community agencies? Scientific developments and medical practice are major factors influencing the kinds and amount of nursing required by patients. The change in the philosophy in the rehabilitation of the cardiovascular disease patient has cut the length of hospitalization. Now he is sent home with a prescribed regimen of medication, diet, rest, and activity. He is encouraged toward activity within his therapeutic and functional classification. He is taught to watch for his own level of tolerance and when to report to his physician.

He is responsible for taking his own medication. Oral diuretics are being perfected and used more generally for maintenance of dry weight. The patient or a member of his family must manage the selection and preparation of a special diet. The success of his treatment depends on the patient's and his family's understanding of the prescribed therapy and their ability to obtain the necessities for carrying it out.

Consequently, the need for nursing services shifts from the hospital to the home. In the hospital the dietary and social service departments join the nursing and medical services to meet the needs of patients. What facilities exist to meet these needs after the patient leaves the hospital?

This study represents a sampling of nursing services given in a community as recorded during 1 calendar month. Comparable studies in other communities with different characteristics and plans of public health nursing administra-

tion are needed in order to identify more completely the nursing services outside the hospital received by patients with cardiovascular disease.

Other studies are needed to determine the specific needs of cardiovascular disease patients outside the hospital; to identify current facilities in the community to meet these needs; and to determine the kinds and amounts of additional services required to meet the special needs of cardiovascular disease patients.

Conclusion

This study in Memphis and Shelby County has shown that nurses employed by tax-supported and private agencies perform services specifically related to the particular diagnosis of cardiovascular disease patients. It has shown also that when frequent visits for the purpose of giving medication are not required, the public health nurse in her usual activities performs services significant to the welfare of the patient with cardiovascular disease. It has demonstrated that agency policy controls the kinds and amounts of services the nurses give patients in this disease category.

The study has further demonstrated that the public health nurse recognizes the emotional and social problems which the cardiovascular disease patient faces when he is outside the hospital.

The study can give nursing educators some guidelines for preparing student nurses better to serve cardiovascular disease patients at home. In addition, it can serve as a basis for developing a continuing inservice plan for staff education in cardiovascular disease control.

ferred for medical care. Of these, 3 patients were referred for emergency medical service, 4 to dental care, and 6 to private physicians. Most of the referrals, 77, were to the city hospitals' outpatient clinic; 3 were to other clinics.

Seventy-two patients (18.7 percent) were given 294 services classed as "general nursing care" during a total of 165 visits. This amounted to an average of 2.3 visits per patient and 1.8 services per visit. Each of the 72 patients received an average of 4.1 general care services.

Sixteen patients (4.1 percent) were referred to community service agencies, but these referrals required 21 visits. One patient was referred to the home teacher service of the board of education.

The fact that a single nursing visit normally was composed of multiple services to one person and that subsequent visits to the same patient might differ in content made interpreting the data difficult. Since scope of service and not quantity alone was to be measured, the specific service item with low frequency might prove to be more significant to cardiovascular disease control than some for which more activity was reported. For example, in this study two patients when visited were found to be pregnant. Since pregnancy represents a stress factor in the woman with heart disease, this observation made early and brought to the attention of the physician could mean prolonged life for the mother. Each item, therefore, maintained its identity in the final tabulations.

All but two services anticipated at the beginning of this study were identified in the patients' records. The observation of the presence or absence of hemorrhage as a reaction to treatment and the administration of penicillin prophylaxis to persons susceptible to rheumatic fever were not reported.

The service most frequently reported was observation of signs and symptoms of congestive heart failure. Slightly more than three-fourths (77.7 percent) of the 1,125 visits recorded during the study included notations regarding these signs and symptoms. In the absence of these symptoms, the nurse may have omitted them from the record.

More than half the patients were under treatment for congestive heart failure. The 10 serv-

ices most frequently given, according to the nurses' records, were related to the treatment of this complication. Diuretics were given intramuscularly or subcutaneously to 197, or 51.1 percent, of the patients. There was indication that teaching about oral and injected diuretics had taken place on visits to 213 patients for whom the medication had been prescribed. The weight of the patient was noted on 106 visits (13.5 percent) at which diuretics were administered in the home.

Oral diuretics were used by 182 patients. On 25 visits nurses noted that patients had experienced gastrointestinal disturbances, a reaction that may have been related to the digitalis or the oral diuretic the patient was taking.

The prescribed digitalis was the basis for three of the services occurring most frequently. These were teaching the patient about the medication, which occurred on 451 visits; observing the practice in taking the drug, reported 385 times; and counting the pulse. The pulse rhythm was noted on 150 visits, or 19.3 percent of the 775 times the pulse was counted.

Other observations such as the dryness of the skin, cramping of the legs, and weakness were also noted in the patient's reaction to his treatment.

Questions and Further Studies

Certain questions about the continuity of care for other patients with cardiovascular disease can be raised as a result of this study. If the 385 patients used the types and amounts of nursing service reported in the 1 calendar month, what happened to the larger number of persons in the community who also had cardiovascular disease?

The prevalence of cardiovascular disease in any given community is difficult to ascertain, since specific diagnostic techniques for all cardiovascular diseases applicable to mass population groups are yet to be developed. Mortality data in cardiovascular diseases are not adequate in determining prevalence but do indicate to some degree the extent of the problem among a population group. In 1956 there were 2,492 deaths from cardiovascular diseases in Memphis and Shelby County; nursing services outside of the hospital were given to only 639 patients in this disease category.

Interviews with a sample of the population in Buffalo, N. Y., revealed that 40 to 50 percent of the adult population had received one or more diagnostic X-ray examinations during the preceding 12-month period; 2.5 to 8.0 percent were therapeutically exposed to X-rays during their lifetime.

Diagnostic and Therapeutic X-radiation in an Urban Population

ABRAHAM M. LILIENFELD, M.D., M.P.H.

DURING 1956, a sample of the population of Buffalo, N. Y., was interviewed to determine the frequency and distribution of selected characteristics as a basis for planning epidemiological studies of cancer. Among the characteristics studied was the extent to which persons were exposed to X-rays in diagnostic examinations and to X-rays or radium in therapeutic procedures.

Since recent discussions of population exposures to ionizing radiation have pointed up the need for precise information of this type, data on examinations and therapy are being reported separately. These data may assist in planning more intensive studies in other geographic areas. In addition, this study should be of interest to those concerned with the distribution of such exposure in the population and its relation to the distribution of leukemia.

Method of Study

Data were obtained by interviewing all persons 18 years of age and older in a sample of households and of persons living in lodging houses in Buffalo. Residents of hospitals, convents, dormitories, and other institutions were excluded. Thus, those interviewed represented

the noninstitutionalized population of Buffalo. In both the households and lodging houses, the samples were selected so that they resulted in a uniform sampling fraction of 1 in 75.

For the household sample, addresses were selected systematically from the Buffalo City Directory of 1956, supplemented by a list of new addresses obtained from the building permits issued by the Buffalo Bureau of Buildings. To take care of omissions from the directory, the "half-open interval method" was used; addresses thus obtained were added to the original lists (1). Separate area sampling studies indicated that a small percentage of addresses were missed by these means.

For lodging houses, a list was obtained from the Erie County Health Department, where lodging houses are registered, and a probability

Dr. Lilienfeld is professor of public health administration, and director, division of chronic diseases, Johns Hopkins School of Hygiene and Public Health, Baltimore, Md. This study, which was supported in part by a research grant from the National Cancer Institute, Public Health Service, was carried out while he was chief of the department of statistics and epidemiology, Roswell Park Memorial Institute, Buffalo, N. Y.

Signs

and

Symptoms

of trends in public health

Tranquille Sanatorium, a tuberculosis treatment center in Victoria, B. C., is to become a school for mental defectives because the mortality rate for tuberculosis is the lowest in history.

“ ”

Poliomyelitis in California During the Pre-vaccine Period, 1910-1954, 72 pp., offers an epidemiological analysis of records of the California State Department of Public Health.

“ ”

An Anti-Coronary Club was organized in 1957 by the New York City Health Department to study the relationship between low-fat diets and low-cholesterol levels with low prevalence of heart disease. Coronary occlusions occurring among its 450 members, some of whom have heart disease, will be compared with those in the general population. A cardiologist and nutritionists from the city health department check weight and diet regularly.

“ ”

The human eye needs twice and sometimes three times as much light as it usually gets in today's living and working conditions, reported University of Michigan's Dr. H. Richard Blackwell after studying lighting for 8 years.

“ ”

It is dangerous to smoke while driving, says the Vision Observation Institute of Philadelphia, Pa. Heavy smoking can produce 10 percent saturation of hemoglobin with carbon monoxide instead of oxygen, and 3 percent can "measurably impair" sharpness of vision and depth perception.

The number of unmarried mothers 15-17 years old increased by 40 percent in the 1946-56 decade, states Katherine B. Oettinger, chief of the Children's Bureau. U. S. Commissioner of Education Lawrence G. Berthick agrees with her that the country's school system should offer more assistance to these unmarried mothers.

“ ”

The National Tuberculosis Association's annual report estimates 69,000 new cases of tuberculosis and 14,000 deaths in 1957 in Americans. There are 150,000 known cases of tuberculosis and perhaps 100,000 others.

“ ”

Dr. Mark Keller and Vera Efron report in the *Quarterly Journal of Studies on Alcohol* that 5 in every 100 Americans past 20 years of age were considered alcoholics in 1956. The total number of alcoholics was 6,269,000. Men outnumbered women 6 to 1.

frequently than women, whereas women were treated more frequently than men. For both men and women in each racial group the frequencies of diagnostic examinations were highest in the younger ages; they decreased with advancing age.

This last finding is surprising, for one would

expect that since the frequency of illness increases with age, diagnostic X-ray examinations would be more frequent in the older age groups. A possible explanation for this age variation would be that young adults are more conscious of health and consequently obtain more X-ray examinations than older adults.

Table 2. Distribution of conditions for which X-ray or radium treatments were given, by sex

sample was drawn maintaining the same sampling fraction.

When the selection of the sample was completed, the addresses were arranged by socioeconomic status. The socioeconomic status of the population was estimated from information on census tracts in Buffalo published by the Bureau of the Census in 1950. The census tract comprises a neighborhood of between 3,000 and 6,000 persons who are relatively homogeneous with regard to such characteristics as median monthly rental, occupational status, and extent of home ownership. The census tracts in Buffalo were ranked according to the median monthly rental as determined in the 1950 census and then assembled into halves so that approximately 50 percent of the city's population fell into each half. The median monthly rental was considered a valid index of relative socioeconomic status because of its high correlation with other indexes such as family income, years of school completed, and occupation.

For white persons in the sample, each address was assigned to its census tract; the assignment determined whether it fell into the upper or lower socioeconomic group. The non-whites were dealt with separately because of their small numbers; however, a large majority of them were in the lower socioeconomic group.

Use of the 1950 census data for assignment of addresses in 1956 might be questioned, but from our knowledge of areas in the city and the social changes that have taken place since 1950, it seems reasonable to expect that those assigned to the lower group are in general of lower socioeconomic status than those assigned to the upper group. In any event, the 1950 census data are the best available for this purpose.

Addresses from both socioeconomic strata were assigned randomly to interviewers.

A total of 4,456 adults were interviewed. About 11 percent of the adults in the selected sample were not interviewed for various reasons: some refused; some were too ill; and others were not at home despite repeated visits by interviewers. To the extent that these 11 percent differ from the 89 percent interviewed, the information obtained is not representative of the population of Buffalo.

As part of the interview, respondents were

asked if, during the preceding 12 months, they had had X-ray or fluoroscopic examinations of the chest, stomach, bowel, teeth, or other part of the body. Each part was specifically mentioned by the interviewer. If a "yes" answer was received, the interviewer then asked the number of times each part was examined. Each respondent was also asked, "Have you ever had any X-ray or radium treatments?" If the respondent replied, "Yes," he was asked what part of the body was treated, when he received treatment (month, year), and for what reasons treatment was given.

In planning the study, it was thought that information on examinations occurring prior to the previous year would be faulty because of defective recall. On the other hand, it was thought that treatment might be sufficiently vivid in a person's lifetime so that it would be less affected by errors of recall, except for treatment received during childhood. Information obtained by interviews is of course subject to error; this will be discussed more fully later in this report. With respect to the possibility of error, it should also be noted that the information about the individual was obtained directly from the person concerned, not from another family member.

In making comparisons among the various groups in this study, differences in their age composition were taken into account by using the direct method of age adjustment commonly employed in routine vital statistics practice (2). The standard population used for age adjustment was the total sample. The rates presented for these groups are adjusted for age and are directly comparable. The numbers in the groups in the tables vary slightly as a result of the variation in the percentage of "don't know" or omitted answers for individual items.

Age, Sex, and Race Distribution

In table 1, the age-specific percentages of persons who stated they had had diagnostic X-ray examinations and X-ray or radium treatments are presented by race and sex. It is notable that between 40 and 50 percent of the population were exposed to one or more diagnostic X-ray examinations during a 12-month period. In general, among adults men were examined more

Table 4. Frequency distribution of all diagnostic X-ray examinations during 12 months preceding interview, by sex, race, and socioeconomic group

Number of examinations	White men						White women						Nonwhite			
	Upper group		Lower group		Both groups		Upper group		Lower group		Both groups		Men		Women	
	Number	Percent	Number	Percent	Number	Percent	Number	Percent	Number	Percent	Number	Percent	Number	Percent	Number	Percent
0.....	493	50.8	463	58.2	956	51.2	679	59.3	609	67.1	1,288	62.8	71	41.8	125	55.6

5-9.....	40	4.1	16	2.0	56	3.2	36	3.1	21	2.3	57	2.8	9	5.3	5	2.2
10-14.....	8	.8	5	.6	13	.7	11	1.0	4	.4	15	.7	1	.6	1	.4
15-19.....	4	.4	0	0	4	.2	2	.2	2	.2	4	.2	0	0	0	0
20 and over.....	4	.4	3	.4	7	.4	1	.1	1	.1	2	.1	0	0	0	0

for white men in the upper socioeconomic group, whereas the reverse is true for the other examinations. Similar white-nonwhite differences are observed for the women except for examination of the bowel. The higher frequency of chest examinations for the nonwhite group may be explained by the higher incidence of tuberculosis among nonwhites or their increased use of public health facilities, such as county hospitals and health department clinics.

The respondents were also asked to tell the number of diagnostic examinations they had received during the year. For both sexes in the white population, about 4 percent had 5 or more examinations during the year; the upper socioeconomic group had more examinations than the lower (table 4). No information was obtained concerning the number of films taken during these examinations. Consequently, estimates of exposure based on frequencies were rather crude. In future studies of a similar nature, this information should be obtained in more detail in order to estimate more accurately the X-ray exposure experience of a population.

During a lifetime, women of both races received X-ray or radium therapy more frequently than men, and the white population of both sexes received more than the nonwhite (table 5). For both sexes, the white upper socioeconomic group had almost twice the frequency of the white lower group.

Thus, the upper socioeconomic group received both more diagnostic and more therapeutic

X-ray than the lower group, which is consistent with the socioeconomic distribution of leukemia.

Distribution by Religion

Recently, MacMahon and Koller reported the interesting observation that the incidence of leukemia among Jewish residents in Brooklyn, N. Y., was about twice that of the non-Jewish residents (5). They considered the possibility that the Jewish population may have been exposed to more X-radiation since there is evidence that Jews receive more medical care than other religious groups in Brooklyn. Despite the fact that the data from Buffalo and Brooklyn may not be comparable, the X-ray exposure experience in Buffalo was analyzed by religious groups to see if the same variation prevailed.

Since the total number of Jews in our sample was relatively small and since the majority

Table 5. Age-adjusted percentages of persons who received X-ray or radium treatments during lifetime, by race, socioeconomic group, and sex

Race and socioeconomic group	Men		Women	
	Number	Percent treated	Number	Percent treated
Total white.....	1,793	6.5	2,068	10.5
Upper group.....	981	8.5	1,157	12.6
Lower group.....	812	4.2	911	7.7
Total nonwhite.....	172	2.0	227	2.6

This seems likely since, as will be noted later, a vast majority of X-ray examinations are of the chest, and probably many of these were part of mass population surveys.

It is also possible that the increasing use of diagnostic X-rays over the past decades is reflected first in the younger age groups, who may have been more likely to accept such innovations and to continue the practice. Therefore, the percentage of exposed individuals in the older ages may increase in the future. The age distribution may also reflect increases in pre-employment physical examinations and membership in health insurance plans.

More of the nonwhites than of the whites had received diagnostic examinations; this is particularly true for the men, among whom this difference is present for all age groups. For the women, the difference between the races is less marked and is not consistent for all ages. Age-adjusted rates for white and nonwhite women are similar.

About 8 percent of the white population and about 2.5 percent of the nonwhites have received X-ray or radium treatments, or both, during their lifetime (table 1). In general, women were more frequently treated.

The frequencies of conditions for which X-ray and radium treatments were given, at least insofar as the respondent was able to recall, are presented in table 2. It is impossible to evaluate the reliability of such information in the absence of medical records. It is of some

importance that many of the conditions for which treatment was received in the past may not be so treated now.

Socioeconomic Distribution

Age-adjusted frequencies of X-ray examination by part of body examined and by race and sex are shown in table 3. For the white population, frequencies are shown also for the lower and upper socioeconomic groups. In view of the current concern over the association of leukemia with ionizing radiation and the observation that leukemia is more frequent in the upper socioeconomic classes than in the lower, exposure to diagnostic and therapeutic X-ray or radium treatment was analyzed to see if it varied in these socioeconomic groups in a manner consistent with the variation in leukemia (3, 4).

From table 3 we note that a large majority of X-ray examinations were of the chest; this is true for both races and both sexes. For all organs examined, men were more frequently examined than women. Also, the frequency of examination is consistently higher for the upper socioeconomic groups for both sexes and for all organ sites. From our knowledge of the social patterns of medical care this is not unexpected.

Comparisons of the white with the nonwhite groups reveal some interesting differences. The frequency of examination of the chest, stomach, and bowel is higher for nonwhite men than

Table 3. Age-adjusted percentages of persons who received one or more diagnostic X-ray examinations during 12 months preceding interview, by site of examination, sex, race, and socioeconomic group

Site of examination	White men			White women			Nonwhite ¹	
	Upper group (N=978)	Lower group (N=801)	Both groups (N=1,779)	Upper group (N=1,152)	Lower group (N=909)	Both groups (N=2,061)	Men (N=172)	Women (N=226)
Chest.....	39.5	35.8	37.9	29.1	24.3	26.8	49.5	31.4
Stomach.....	6.6	5.4	6.1	5.6	5.4	5.5	8.9	6.0
Bowel.....	4.4	3.6	4.0	3.4	2.2	2.9	5.1	2.2
Teeth.....	11.8	6.5	9.4	12.4	6.3	9.6	4.8	3.7
Other.....	8.9	7.4	8.2	7.2	6.2	6.7	6.5	4.4
All sites.....	49.6	41.7	46.0	41.8	32.9	37.7	57.9	37.6

¹ The small number of nonwhites in this study prevented any meaningful distinction between upper and lower socioeconomic groups.

Sex differences in leukemia mortality are not large, the male-female ratio being about 1.1 to 1.2. The sex differences in frequency of diagnostic and therapeutic X-ray procedures revealed that men had more X-ray examinations than women, and the women had more X-ray therapeutic procedures than men. Perhaps a balancing of these two might result in a total excess exposure of women, particularly since total dose for treatment is probably greater than for diagnostic examinations.

Leukemia is more frequent among whites than among nonwhites; again, the difference is not large. MacMahon and Koller think that this difference is a result of the greater frequency of diagnosis of leukemia among whites than among nonwhites rather than a difference in the true incidence of the disease (5). Frequency of diagnostic and therapeutic X-ray procedures disclosed that nonwhites had more diagnostic but much fewer therapeutic exposures than whites. As with sex differences, perhaps total exposure was greater among whites than among nonwhites.

In contradistinction to the sex and racial differences in the frequency of leukemia, the Jewish and non-Jewish and the socioeconomic group differences are of a larger order of magnitude. Thus, the large differences in X-ray exposure by religion and socioeconomic groups are consistent with large differences in the frequency of leukemia between these segments of the population. While the findings have not been analyzed in a more refined quantitative manner (a procedure not warranted by these data), their consistency points up the need for further study of the relationship of leukemia to the above-mentioned population groups, of radiation exposure to the same groups, and of the association of leukemia with exposure to ionizing radiation.

Summary

During 1956, a probability sample of the adult population of Buffalo, N. Y., was interviewed on the frequency of diagnostic X-ray examinations during a preceding 12-month period, and of X-ray or radium therapy during a lifetime. About 50 percent of the adult population had had one or more diagnostic X-ray

examinations during the 12-month period. Male members of the population had such examinations more frequently than the female members of both races, and for both sexes the nonwhites had received examinations more frequently than the whites. Individuals of both sexes in the upper socioeconomic group received X-ray examinations more often than those in the lower group.

Analysis of the frequency of therapeutic procedures revealed that about 8 percent of the white population had received such exposure during a lifetime compared with 2.5 percent of the nonwhite population. Women of both races had a higher frequency of such treatment than men. For both sexes of the white population, the upper socioeconomic group had such procedures more frequently than the lower group.

The frequency of both X-ray examinations and therapeutic procedures was higher among the Jewish members of the population than among the non-Jewish members. The distribution of X-ray examinations and therapeutic procedures by religion and socioeconomic group was similar to the distribution of leukemia.

Studies are needed in other geographic areas to obtain more detailed information concerning exposure to therapeutic and diagnostic radiation than was possible in the present investigation.

Women.....	634	39.7	610	12.5

of them were in the upper socioeconomic group, comparison by religion was limited to the upper socioeconomic group (table 6). For both sexes, Jews had more diagnostic X-ray examinations and more X-ray therapy than the other religious groups. The differences were not large with regard to examinations, but the therapeutic procedures were almost twice as frequent among Jews as among non-Jews. The importance of this observation lies in its consistency with the distribution of leukemia by religion. A possible explanation for the frequency of therapy among Jews may be that the Jewish group was in a relatively higher socioeconomic segment of the upper socioeconomic group. Unfortunately, the number of Jews was too small to permit further study.

Discussion

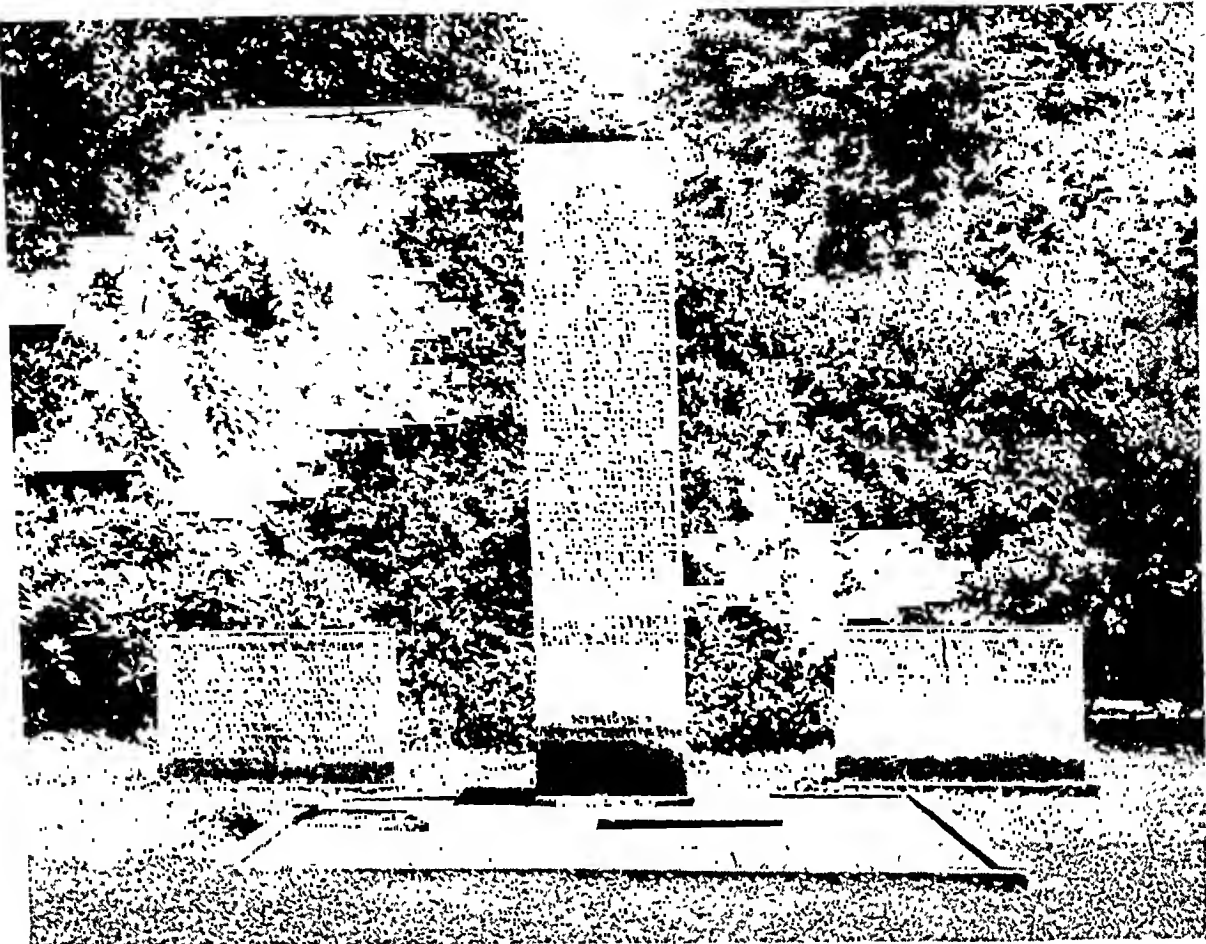

The results of the present study can be considered from two viewpoints. First, they provide some idea of the frequency of exposure of an urban population to diagnostic and therapeutic radiation. Second, they indicate that the frequencies of such exposure are related to several characteristics of the population found previously to be associated with the distribution of leukemia.

In evaluating the estimates of exposure several points must be borne in mind. The estimates may be minimal since, as has been mentioned, some individuals may not have been able to recall all their exposures to X-rays. On the other hand, some may have overestimated the frequency of diagnostic X-ray examinations: the data were obtained for a period of 12 months preceding the interview and there may have been a tendency for some to state that they had been X-rayed during the past year even though the exposure actually occurred earlier. Such a phenomenon has been observed in morbidity surveys (6). It is therefore difficult to determine the validity of these estimates without medical records. This particular objection does not apply to the frequency of therapeutic procedures. The respondents were asked to provide information on therapy during their lifetime and the only error would lie in underestimation, although it is possible that some individuals may have experienced non-X-ray procedures (such as diathermy) which they erroneously thought were X-ray procedures, or they may have confused diagnostic with therapeutic radiation.

Keeping these difficulties in mind, it still appears that this particular urban population was exposed to a large amount of diagnostic and therapeutic radiation. The frequencies seem so large as to indicate a definite need for repeating similar and more detailed population surveys specifically designed to reveal the extent of exposure. In such studies, it would be essential to establish procedures for determining the validity of the estimated frequencies.

The second point of interest in these results was the distribution of X-ray exposure in different segments of the population. Diagnostic examinations were more frequent among non-whites than whites, men than women, persons in the upper socioeconomic group than those in the lower, and among Jews than non-Jews.

Some of these differences are consistent with the distribution of leukemia in the population. For example, leukemia mortality is higher among persons in the upper socioeconomic group and among Jews. Consistency with regard to sex and racial differences is difficult to evaluate.

Radiation Martyr Memorial, Hamburg, Germany

ciple reaffirmed by Dr. Wendell G. Scott, professor of clinical radiology, Washington University School of Medicine, St. Louis, at a session of the American Medical Association meeting, June 1958, in San Francisco. Scott said, "No matter what the present average gonadal dose in X-ray examinations is, it is too high if it can be lowered."

The policy of the college was outlined in 1956 in the following statement:

"The American College of Radiology will cooperate with all efforts to encourage medical authorities of this country to initiate a vigorous movement to reduce radiation exposure from X-rays to the lowest limit consistent with medical wisdom, and in particular that they take steps to assure that proper safeguards always be taken to minimize the radiation dose to reproductive cells. Radiologists spend long periods in special training and in acquiring ex-

perience to foster judgment in the use of radiations.

"Appropriate training and experience must be insisted upon for all users of radiation. For all, adequate stress must be placed on protection and safety aspects of the use of radiations in human beings. . . . Certain it is that we all desire to keep the dose of radiation to its lowest level to the population that is well. The dose of radiation to those who are ill and require either studies or treatment with radiation should also be kept as low as possible, but here the conditions for judgment are different. In this case, we give as little radiation as possible in order to achieve the desired end of proper diagnosis or treatment; but when, in a careful radiologist's judgment, an individual patient requires a dose exceeding 10 roentgens or any other arbitrary figure, his medical judgment must prevail. One way of keeping diagnostic

Medical Radiation

ALTHOUGH most of its program was given to papers on diagnosis and therapy, the 1958 meeting of the American Roentgen Ray Society in Washington, D. C., opened September 30 with talks on radiation hazards. Dr. Robert R. Newell, U. S. Naval Radiological Defense Laboratory, San Francisco, evaluated clinical exposure, saying, "It is not sensible to stop using diagnostic methods of obvious value for fear of radiation injuries that are unobservable among the ordinary vicissitudes of life. The common-sense solution is to amend the techniques." He recommended that radiologists "tighten up the techniques, starting at the high end, and at the same time undertake more popular education, starting at the low end." He also said it is necessary to get people to stop holding their breath over radiology and to get radiologists "to pant a little bit while they chase around and clip off the needless margins of their diagnostic exposures."

The role of the radiologist as a citizen, with respect to public exposure, was expounded by Dr. George Tievsky, clinical instructor in radiology, George Washington University School of Medicine, Washington, D. C. So that existing knowledge may be applied to the minimization of radiation hazards in clinical practice, he recommended that local radiological groups distribute a questionnaire based on Handbook 60 of the National Committee on Radiation Protection to determine the current pattern of radiation management. He reported that such a survey conducted by the section on radiology in the District of Columbia Medical Society had a good educational effect and also brought out opportunities for improving techniques.

Tievsky urged support of the educational program of the American College of Radiology, described below, to minimize radiation hazards at the hands of others than the trained radiologist. This recommendation raised the question

of consideration by the medical profession of standards of experience and performance for general practitioners and others employing radiation. He also discussed applying Handbook 60 standards to all fluoroscope and X-ray installations and the mastery by radiation users of the fundamentals of biology and dosage given in Handbook 59 (NCRP).

During the meeting, Dr. Barton R. Young, president of the American Roentgen Ray Society, on a national television program, expressed the need to allay hysterical public fears of legitimate X-ray uses in diagnosis and therapy. He emphasized the fact that under proper professional supervision certain parts of the body may be exposed to X-ray repeatedly without exceeding prudent limits. He also emphasized that there is no need to be apprehensive of genetic damage in patients who are unlikely to become parents.

Among the scientific exhibits at the conference was one devoted to elements of radiation protection, sponsored by Drs. Richard E. Petersen, Julius Baron, Bartis M. Kent, and Titus C. Evans, Veterans Administration Hospital, Iowa City. Prominently displayed in this exhibit was a photograph (see page 37) of a memorial to radiation martyrs of all nations at St. George's Hospital, Hamburg, Germany. Unveiled April 4, 1936, the monument has the names of 197 persons, including physicians, technicians, and nurses. More names are to be added. Visitors to the exhibit were given a mimeographed Primer on *Radiation Hazards for Physicians*, produced in collaboration with the radiation research laboratory and department of internal medicine in the Medical College of Iowa.

Coincident with the meeting of the American Roentgen Ray Society, the American College of Radiology reported on its educational activities. These activities are guided by a prin-

Radiation Research

CONFERENCE REPORT

ON THE SAME DAY the United Nations released its report expressing scientific agreement on the probability of harmful consequences to public health from nuclear weapons tests, August 10, 1958, the University of Vermont at Burlington welcomed the International Congress of Radiation Research, sponsored by the Radiation Research Society and the National Academy of Sciences-National Research Council.

Presided over by Alexander Hollaender, Oak Ridge National Laboratory, the conference did not give much attention to ecologic or environmental contamination. The primary interest of most of the scientists present was in basic aspects of radiation action from the physical, chemical, and biological point of view.

Papers presented to the conference bore such titles as "Autoradiograph of the Nucleus in Metabolic State" (Pavan and Ficq) or "Postirradiation Release of Phosphorus by Yeast" (O'Brien). Abstracts of most of the papers presented were published in advance of the meeting. The symposiums are to be published in full.

Through a series of interviews arranged by the university and conference officials, informal statements and conclusions of public interest were elicited from the scientists by reporters representing the wire services, broadcasters, major daily papers, and science news services. As a result, findings by the scientists reached television, radio, and newspaper audiences, as

well as readers of the science press. In appreciation, an unusual tribute to the competence and accuracy of the reporters was paid by the presiding officer at the closing session.

Among items reported to the public were the following:

★ If there is a threshold dose of radiation for shortening life or for the production of leukemia or other forms of cancer, it is probably so low as to be of no great practical significance for public health, said H. J. Curtis, Brookhaven National Laboratory, who doubts there is any threshold at all. A. M. Brues, Argonne National Laboratory, doubted that microdoses reduce life span.

★ Radiation is unique as a life-shortening agent, Curtis and K. L. Gebbhard, also of Brookhaven, concluded after tests which sought and failed to establish life-shortening effects of other nonspecific stresses in mice. They also discovered, after using nitrogen mustard to induce mutations in somatic cells, that the mice recovered from such mutations and lived as long as others. They concluded therefore that somatic mutations induced by radiation are not decisive in the aging process.

★ The average life span of certain mice exposed to low doses of radiation exceeded the average of unirradiated mice, reported L. D. Carlson and B. H. Jackson of the University of Washington, although the longest lived of the unirradiated mice survived the others. Above a given level of radiation, average expectancy

dosage to a minimum is to make every effort to have a given examination done right the first time. It should be emphasized that genetic considerations do not apply to patients who are past the reproductive period or who die without issue after receiving radiation."

The National Committee on Radiation Protection and the International Commission on Radiation Protection have for many years formulated the standards for protection of patients, the public, and personnel engaged in medical diagnostic procedures. So that the entire medical profession be acquainted with such recommendations and with basic information on the physical, radiobiological, genetic, and radiological aspects of the medical use of X-ray, including knowledge of the proper indication for X-ray examinations and the most effective way of performing them, the American College of Radiology has undertaken dissemination of this information to everyone engaged in the healing arts.

Lectures, symposiums, and panel discussions on these subjects have been sponsored by the college at the meetings of local, State, and national medical organizations. These are conducted by experts in radiation physics, radiobiology, genetics, and radiology. The lectures and discussions are published in medical journals, and reprints are distributed to the medical profession by the thousands.

The college has prepared and distributed a Practical Manual on the Medical and Dental Use of X-Rays With Control of Radiation Hazards to 175,000 practicing physicians in the United States. This manual contains basic information brought out by the National Academy of Sciences and the United Nations as well as practical clinical recommendations. It was also sent to all editors of county, State, and national journals. Another 30,000 copies will be distributed to all interns and resident physicians.

Sets of colored slides illustrating the control of the hazards of radiological examinations and explaining the most exact methods of radiographic examinations have been prepared by the college and are available to any physician

who requests them. Several hundred of these slide sets are in use, and new ones are sent out nearly every day for medical groups.

A protection kit has been designed by the college for the same application. It includes reprints of important lectures and papers, with a prepared lecture to help radiologists and other physicians talk on this subject before medical groups. More than 1,000 of these kits have been distributed.

A documentary motion picture film for the medical profession about radiation protection and the proper use of radiological procedures is being financed in part by the college, with support by a grant of \$65,000 from the Rockefeller Foundation.

The objectives of these educational efforts are to:

1. Develop a calm and mature attitude toward the nuclear era, an era that holds great promise for the betterment of mankind.
2. Put an end to unwarranted concern about medical radiation and stop confusion between it and thermonuclear warfare, the latter's massive or chronic whole body irradiation, and occupational exposure to radiation.
3. Have every physician using diagnostic radiology exert positive efforts to keep radiation dosage to the gonads to the lowest level consistent with the best standards of medical practice.
4. Achieve recognition of the fact that radiation to the germinal tissues can be reduced in some instances by 75 to 85 percent without impairing the efficiency of diagnostic examinations and achieve this reduction universally within a short time.
5. Gain realization that the key to implementing the safe use and control of medical radiation lies in the education of all practicing physicians in the fundamentals of genetics, radiobiology, and radiology.

The American College of Radiology is the official spokesman for organized radiology in relations with other organizations, and its principal interest is the socioeconomic aspects of radiological practice. It maintains close liaison with the scientific radiological societies such as the American Roentgen Ray Society.

the faculty of neutralizing free radicals (defined as "molecules looking for electrons") formed in the process of ionization. Although it was emphasized there is no broad public protection visualized in the use of these chemicals, they may have some value for patients undergoing radiation treatment and for workers who must encounter extreme radiation dangers, according to D. G. Doherty and R. Shapira, Oak Ridge National Laboratory.

★ Radiation damage to bone marrow can to

some degree be treated by injections of bone marrow, it was reported by many of the scientists, who held a roundtable on the topic. This announcement opened speculation on the desirability and methods of building banks of fetal bone marrow, the kind most suitable for treating acute injuries. Prevailing judgment in the discussion concluded that bone marrow injections are still quite hazardous and that other therapy should be attempted first, except in the most serious cases.

First Annual NHS Report on Illness

The first annual report on illness, injuries, and physician visits in the United States has been issued by the U. S. National Health Survey, Public Health Service, based on interviews covering 36,000 homes and 115,000 persons during July 1957-June 1958. The continuing survey, authorized by the 84th Congress, is conducted among both institutional and noninstitutional segments of the civilian population, but this report presents major findings only for the noninstitutional segment. More detailed individual reports are scheduled for the future. The following are some highlights of the report.

There were 3,370 million days of restricted activity due to illness or injury, or 20 days per person per year. Days in bed because of illness or injury numbered about 1,310 million, or an average of 7.8 bed-disability days per person a year.

About 438 million cases of acute conditions occurred during the year, with respiratory illnesses ranking first and injuries second as a cause of work-time loss. The 284 million respiratory illnesses included colds, pneumonia, and influenza. In this incidence Asian influenza figured prominently. The incidence of acute conditions was slightly higher among females than males and decreased with age.

Although tabulations for chronic conditions were incomplete, the data showed that circulatory conditions caused 484 million days of restricted activity, 167 million days of bed disability, and 69 million days of work loss.

Physician visits were estimated to be 890 million, about two-thirds in offices, and more in the October-December quarter than during any other period. The survey estimated about 4,000 visits per doctor, based on 220,000 practicing physicians.

declined. The results were affected also by temperature. They concluded there is an interaction between radiation and environment which affects radiation reactions. Others reported that the average life span of lightly irradiated mice was shortened.

* G. W. Casarett, University of Rochester, observed marked acceleration in the aging of dogs exposed to doses of 3 roentgens weekly. The aging process was not obvious in dogs receiving only a tenth or a fifth as high a dose.

* The mechanism of radiation injury was described by L. A. Stocken, Oxford, as interference with the assembly line operation in metabolism. The production of high-energy phosphates, he said, is stopped, presumably through injury to critical enzymes in the cellular system. He did not believe that radiation injury results from an accumulation of stresses or insults and did not think it is related to the oxygen supply.

* To insure human survival against consequences of excessive injury to genetic cells in a nuclear holocaust, H. J. Muller, Indiana University, speculated on the need for banks of human sperm and ova that might be preserved and shielded against radiation.

* In Russia, radiation sickness is detected by clinical methods, held to be five times as sensitive as the blood tests in use in the United States. Headaches, fatigue, dryness of the mouth, and unusual perspiration are observed, after a daily exposure to 0.02 roentgen over a 6-month period, it was said by M. N. Pobedinsky, Central Radiological Institute, Leningrad.

* A nuclear power plant, properly designed and operated, can operate safely near a supply of drinking water, but the place for disposition of waste from spent fuel in the reactor may lie only in outer space, in the opinion of R. H. Mole, Medical Research Council, Atomic Energy Research Establishment, England. He proposed a form of international control over disposition of radioactive waste, since the failure of any single government to manage wastes safely can affect the entire world.

* Mole said that in his judgment the production of obvious defects, such as cancer, results from relatively acute doses, rather than from low-level chronic doses comparable to the

Delegates to the radiation congress witnessed films demonstrating that certain species are capable of sensing the stimuli of intense radioactivity. In the presence of high-level irradiation, snails pulled their heads into their shells, and ants fled from an open pen into a lead-shielded one.

levels of radiation from the natural background. Without implying that low-level chronic irradiation is inconsequential, he asserted that the major concern of public health should be directed at relatively acute doses. He expressed apprehension lest the expanding uses of nuclear power increase the likelihood of acute doses and was critical of unwarranted administration of acute X-ray doses by negligent or incompetent practitioners. In support of his comments, he referred to the recently published Stewart studies of children under 10 years of age with cancer diseases: 10 percent had a history of exposure of the order of 2 roentgens over the whole body in about an hour.

* The relative importance of acute doses was reported also by W. L. Russell, Oak Ridge National Laboratory, with respect to genetic effects. The effect on spermatids of 600 roentgens given in a few minutes was much greater than the effect of the same dose over a period of 6 weeks.

* To judge by radiation's effects on mice, Curtis suggested that a searching fluoroscopic examination of an expectant mother probably cuts 2 weeks from the longevity of the infant.

* Females are more likely to be sterilized by a given dose of radiation than males, said L. B. Russell, Oak Ridge National Laboratory, to judge by effects on experimental mice. (Males, however, are more vulnerable to genetic injury.)

* Twenty different radioactive nuclides were identified in plankton and sessile algae from a site 1 mile below the Hanford reactor farthest downstream, reported J. J. Davis of the Hanford Laboratories. Only five of the nuclides, however, were picked up by fish.

* Partial protection against radiation effects on bone marrow, for persons exposed deliberately to acute radiation, may be provided by certain inexpensive chemicals, swallowed half an hour before exposure. The chemicals have

concentrate in a relatively small volume of tissue, the thyroid gland, and milk certainly constitutes the major dietary item for infants and children. The net result would be the deposition of radioactive iodine in the thyroids of children in much higher concentration than in the adult population.

It was necessary to condemn about 250,000 gallons of milk from about 600 herds of cattle, over an area from 200 to 300 square miles. The population of the area was approximately 100,000 people. Because of the short half-life of iodine-131, the emergency situation lasted about 2 or 3 weeks. It should be pointed out that this milk could have been used for manufacturing purposes or the feeding of livestock but, because of public apprehension, it was decided not to salvage the milk.

The accident created an extraordinary degree of disturbance. One outcome was recognition of the need for more public as well as scientific understanding of the risks associated with such an incident and for considerably more competence in health and safety as related to atomic radiations.

Recent evidence indicates that the thyroid glands of infants and young children, contrary

to previous belief, are relatively sensitive to radiation. The dosages to children's thyroids closest to the areas in which the milk was condemned were in the order of 10 rad. The unresolved question, therefore, is whether or not the carcinogenic effect associated with radiation exposure of the tissue is a threshold phenomenon. To date there are good epidemiological data indicating that radiation levels as low as 150 rads are associated with a significant incidence (in the order of 1 percent) of thyroid cancer.

As previously pointed out, the radionuclide receiving almost exclusive attention as an internal radiation hazard had been strontium-90. However, it should be remembered that there are other sources which should be considered in evaluating the total dose. The recent report by the Public Health Service on its radioactivity surveillance of milk in selected milksheds supports this point. Although the reported levels of milk radioactivity are appreciably below the presently accepted permissible levels, over the past year the relation of iodine-131 to its permissible levels has been almost the same as that of strontium-90 to its permissible levels.

Certain Food Additives Listed as Safe by FDA

A list of 188 food chemicals, generally regarded as safe for their intended use, has been proposed by the Food and Drug Administration for exemption from testing required by law. The list appears in the *Federal Register*, December 9, 1958, pp. 9516-9517, along with regulations proposed in compliance with the 1958 Food Additives Amendment to the pure food law.

Including some already sanctioned for use, the group comprises 61 preservatives, 39 buffers and neutralizers, 35 nutrients, 5 non-nutritive sweeteners, 5 coloring agents, 5 stabilizers, 4 emulsifiers, and 34 other additives. Thirty-six are limited as to quantity or foods in which they may be used. Other chemicals may be added if they meet the legal criteria.

The proposed regulations take into account that a chemical might be both a new drug and a food additive, in which case only one petition need be filed.

Milk Contamination in the Windscale Incident

ARTHUR H. WOLFF, D.V.M.

RADIOACTIVITY in foodstuffs, particularly milk, is a new public health consideration associated with the atomic age. To my knowledge, the first situation in which radioactivity was reported in milk in sufficiently high concentration to be of immediate concern was the "Windscale incident," which occurred in England on October 10, 1957.

Windscale is located in the northwest corner of England on the Irish Sea. The British Atomic Energy Authority operated a breeder-type nuclear reactor in Windscale which when overheated resulted in a uranium fire. Because the reactor was air-cooled, the air going out the exhaust stack carried with it vast quantities of fission products. The accident admittedly occurred because of faulty instrumentation and human error; the fire was in progress for 24 hours before adequate diagnosis of the situation was made. It should be pointed out, however, that the Windscale reactor is obsolete by present standards. Newer reactors of this type have built-in control and safety features which greatly reduce the probability of such an event recurring.

There are many different radionuclides contributing to the usual spectrum of gross fission products. The one that has received the most public health attention is strontium-90, but it is not too well appreciated that there are other radionuclides to be considered in evaluating the public health aspects of nuclear fission. Radioactive iodine, in particular iodine-131, is a sig-

nificant component of freshly produced fission products. At Windscale a disproportionate amount of the iodine, because of its volatility, was driven off as a result of the fire, bringing about environmental contamination. Only a small fraction of the many other fission products escaped from the stack.

As soon as the situation was recognized, the immediate concern of the health and safety authorities was the possibility of a fallout from the stack exhaust which could result in hazardous levels of external radiation in the downwind area. An immediate evaluation of the downwind external radiation levels was ordered. In the interim, the local constabulary was alerted to assist in an evacuation of the residents in the affected areas if deemed necessary. It was soon determined that the levels of external radiation were extremely low.

The next consideration was the possibility of milk being contaminated. Cattle had been in the fallout area and possibly had ingested contaminated pasture. This fear was realized. Analysis of milk indicated that high levels of radioactivity, most of which was ultimately identified as iodine-131, was being secreted in the milk of the dairy cattle in the fallout area.

The authorities soon realized that they were confronted with a serious problem of milk contamination for which there were no standards of emergency permissible levels that could be appropriately applied. British authorities, guided by certain biological considerations and the exigencies of the situation, set up an emergency permissible level of 0.1 microcurie of iodine-131 per liter of milk and then set up a wide-scale sampling program to delineate the affected milksheds.

The occurrence of radioactive iodine as a contaminant and milk as the vehicle compounded the seriousness of such an incident. Iodine will

Dr. Wolff is chief of the Training Branch of the Division of Radiological Health, Public Health Service. The paper was given at the Communicable Disease Center Conference for Teachers of Veterinary Public Health and Preventive Medicine and Public Health Workers on June 12, 1958, in Atlanta, Ga.

Tests with serums of 248 leprosy patients showed that, in differentiating syphilitic from biologic false-positive reactors, the RPCF test is as reliable as the TPI test.

Reactivity of the RPCF Test in Leprosy Compared With Other Syphilis Tests

GEORGE R. CANNEFAX, B.S., SISTER HILARY ROSS, B.S., and HULDAH BANCROFT, Ph.D.

LEPROSY stands high on the list of clinical entities known to produce biologic false-positive reactions with the conventional serologic tests for syphilis. Of the many procedures which have been used for the differentiation of the BFP reactor from the syphilitic reactor the *Treponema pallidum* immobilization (TPI) test has been considered to be the most reliable. The data presented in this paper indicate that in persons with leprosy, the Reiter protein complement fixation (RPCF) test is as reliable as the TPI test in differentiating syphilitic and biologic false-positive reactors.

The several serologic tests for syphilis employing lipoidal antigens are known to produce varying degrees of biologic false-positive re-

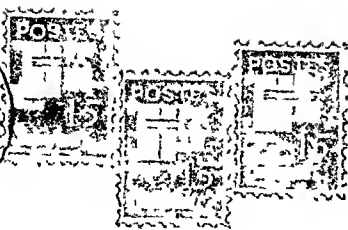

sults with the serum of leprosy patients. In comparative studies in which crude tissue extract and cardiolipin antigens have been used, the percentage of biologic false-positive reactors has been found to be less with tests employing cardiolipin antigens. However, none of the efforts to eliminate these biologic false-positive reactions by refinement of antigen or other modifications has been completely successful.

Studies have been made of the use of Reiter treponemes in complement fixation tests for syphilis to provide information concerning the reliability of these tests when employed with serum from patients with leprosy. Two such studies in which suspensions of whole Reiter organisms were used as antigen in the complement fixation tests for syphilis with leprosy patients have been reported by Eagle and associates (1) and by Kolmer and associates (2). In both of these studies patients at the Public Health Service Hospital, Carville, La., were the source of their testing material. These reports, which may be considered representative of reports from several sources, indicated that the use of antigen consisting of whole Reiter treponemes produced what was considered an undesirable percentage of false-positive results.

The TPI test was applied by Nelson (3) to the serums of 57 Carville patients who were reactive with a complement fixation test employing cardiolipin and with the VDRL slide test. Sixteen of the 57 serums immobilized the trep-

Mr. Cannefax is a bacteriologist with the Public Health Service Venereal Disease Experimental Laboratory at the University of North Carolina School of Public Health, Chapel Hill, N. C. Sister Hilary Ross is the biochemist in charge of the laboratory of the Public Health Service Hospital, Carville, La. Dr. Bancroft is professor of biostatistics, department of tropical medicine and public health, Tulane University, New Orleans, La.

Dr. E. B. Johnwick, medical officer in charge, and Dr. R. R. Wolcott, clinical director, Public Health Service Hospital, Carville, provided clinical information and material for this study. Mrs. Marie B. Nifong and Mrs. Frances T. Moon gave technical assistance in performing the treponemal tests.

The 13th Round

By early 1959 we hope to end the yaws campaign in Esmeraldas Province, Ecuador, and turn over responsibility for residual cases to the ordinary health services. Eradication is virtually complete in the southern part of the province. The only active cases are appearing in the north, along four rivers, where the efforts of the 13th house-to-house round are being concentrated.

—JAMES D. CALDWELL, *chief, Health Division, U. S. Operations Mission, Ecuador.*

Cholera and Smallpox

Before the monsoon began in June 1958, we were fighting cholera and smallpox in East Pakistan. Cholera cases averaged 150 to 200 a week, and smallpox, 1,700 cases and 850 deaths a week.

In April, the Provincial Government asked for help in combating smallpox, and within 2 months a total of 28.4 million doses of smallpox vaccine, sent by 17 countries and the World Health Organization, arrived here. About half the vaccine was distributed and the rest stockpiled.

A United States Navy medical research team based in Taiwan and nine epidemiologists from the Communicable Disease Center in Atlanta, Ga., headed by Dr. Alexander D. Langmuir and Dr. Glenn S. Usher, came in response to the Pakistani Government's request for additional personnel to control the epidemics.

The Navy team began research on cholera and studied the effectiveness of smallpox vaccine after varying periods without refrigeration. The epidemiologists studied the extent of the cholera and smallpox epidemics, the effectiveness of the smallpox vaccinations, and the percentage of those effectively vaccinated.

Reports of this work indicated the practicability of smallpox eradication. We now have ample supplies of vaccine and the people are receptive to the neces-

sary measures. We plan to try various ways to persuade more people to be vaccinated. Each woman will be given the sewing needle used to vaccinate her. Teams of women vaccinators will operate where purdah is observed.

The field tests showed the usefulness of the dried vaccine in East Pakistan. In the past, lack of refrigeration and transportation forced vaccinators to use vaccine lymph of questionable potency, and vaccinating was suspended in the summer months in some parts of the country. The dried vaccine, requiring refrigeration only after it is mixed, will make it possible to vaccinate throughout the year.

We arranged to set up a plant which will prepare dried smallpox vaccine for East Pakistan and to supply a consultant to install the equipment and instruct the Pakistanis who will operate it.

Control of cholera may take years, since it depends upon improvement of water supplies, general sanitation, and health education. Until this is achieved, we can only hope to limit the number of cases.

—JOHN A. BELLIZIA, *acting chief, Health and Sanitation Division, U. S. Operations Mission, East Pakistan.*

Decentralization

I went to Neyriz, a town of 12,000 in Fars Ostan, Iran, to take a trained sanitary aide to his new post and to introduce him to the mayor and the council, who are extremely interested in improving sanitation. While there we selected a site for the slaughterhouse for which 200,000 rials are allocated. They have also submitted a candidate to go to the Palasht School for training sanitarian aides.

The response in Neyriz is typical of other municipalities in Fars Ostan. Their demand for sanitarians exceeds the supply. The idea of local responsibility for public health services seems to be catching on; 6 municipalities have submitted candidates for Palasht.

However, we refuse to place a trained sanitarian aide in a town if we cannot get a satisfactory commitment that the town will assign a qualified municipal employee who will work with the aide and then go to Palasht himself the following year. Thus we get the maximum use out of the training given the people in our placement program.

—DAVID S. REID, *sanitary engineer, U. S. Operations Mission, Iran.*

Tests with serums of 248 leprosy patients showed that, in differentiating syphilitic from biologic false-positive reactors, the RPCF test is as reliable as the TPI test.

Reactivity of the RPCF Test in Leprosy Compared With Other Syphilis Tests

GEORGE R. CANNEFAX, B.S., SISTER HILARY ROSS, B.S., and HULDAH BANCROFT, Ph.D.

LEPROSY stands high on the list of clinical entities known to produce biologic false-positive reactions with the conventional serologic tests for syphilis. Of the many procedures which have been used for the differentiation of the BFP reactor from the syphilitic reactor the *Treponema pallidum* immobilization (TPI) test has been considered to be the most reliable. The data presented in this paper indicate that in persons with leprosy, the Reiter protein complement fixation (RPCF) test is as reliable as the TPI test in differentiating syphilitic and biologic false-positive reactors.

The several serologic tests for syphilis employing lipoidal antigens are known to produce varying degrees of biologic false-positive re-

sults with the serum of leprosy patients. In comparative studies in which crude tissue extract and cardiolipin antigens have been used, the percentage of biologic false-positive reactors has been found to be less with tests employing cardiolipin antigens. However, none of the efforts to eliminate these biologic false-positive reactions by refinement of antigen or other modifications has been completely successful.

Studies have been made of the use of Reiter treponemes in complement fixation tests for syphilis to provide information concerning the reliability of these tests when employed with serum from patients with leprosy. Two such studies in which suspensions of whole Reiter organisms were used as antigen in the complement fixation tests for syphilis with leprosy patients have been reported by Eagle and associates (1) and by Kolmer and associates (2). In both of these studies patients at the Public Health Service Hospital, Carville, La., were the source of their testing material. These reports, which may be considered representative of reports from several sources, indicated that the use of antigen consisting of whole Reiter treponemes produced what was considered an undesirable percentage of false-positive results.

The TPI test was applied by Nelson (3) to the serums of 57 Carville patients who were reactive with a complement fixation test employing cardiolipin and with the VDRL slide test. Sixteen of the 57 serums immobilized the trep-

Mr. Cannefax is a bacteriologist with the Public Health Service Venereal Disease Experimental Laboratory at the University of North Carolina School of Public Health, Chapel Hill, N. C. Sister Hilary Ross is the biochemist in charge of the laboratory of the Public Health Service Hospital, Carville, La. Dr. Bancroft is professor of biostatistics, department of tropical medicine and public health, Tulane University, New Orleans, La.

Dr. E. B. Johnwick, medical officer in charge, and Dr. R. R. Wolcott, clinical director, Public Health Service Hospital, Carville, provided clinical information and material for this study. Mrs. Marie B. Nifong and Mrs. Frances T. Moon gave technical assistance in performing the treponemal tests.

Table 1. Number of negative results with five serologic tests of serum specimens from 248 leprosy patients

Number of tests negative	TPI	RPCF	TPCF	VDRL	Kahn	Number of patients	Percent of patients
5-----	-	-	-	-	-	130	52.4
	+	-	-	-	-	1	.4
4-----	-	+	-	-	-	1	.4
	-	-	+	-	-	{ 21	8.5
	-	-	-	+	-	5	2.0
	-	-	-	-	+	24	9.7
3-----	-	-	-	+	+	45	18.2
	-	+	+	-	+	1	.4
	-	-	+	-	-	1	.4
2-----	+	-	+	+	+	7	2.8
	+	-	+	-	+	1	.4
	+	-	-	+	+	4	1.6
1-----	+	+	+	+	+	1	.4
	+	-	+	+	+	1	.4
0-----	+	+	+	+	+	5	2.0

onemes. None of the 57 patients had anamnestic or clinical evidences of syphilis. The frequency of reactors with the TPI test with this group was interpreted by Nelson to be more or less indicative of the syphilis to be expected in the racial and socioeconomic groups from which the patients were drawn.

Edmundson and associates (4) made a clinico-serologic study of 224 Carville patients comparing the results of the TPI test with several conventional serologic tests for syphilis. Reactivity percentages were as follows: TPI, 11.2; VDRL, 46.9; Rein-Bossak, 51.8; Kahn, 52.7; and Kolmer (cardiolipin), 63.4. It was concluded that the TPI results were much more consistent with opinions regarding the prevalence of syphilis in this population than were the results of the other tests.

D'Alessandro and Dardanoni (5) tested 19 patients with leprosy and found 9 reactive with the Kahn test, 8 reactive with a complement

fixation test employing whole Reiter treponemes as antigen, 6 reactive with a cardiolipin complement fixation test, and 4 reactive with the full-volume Kolmer test employing Reiter protein antigen. The status of these patients in relation to past or present syphilis infection was not given.

Previous testing in the Venereal Disease Experimental Laboratory with the RPCF test has demonstrated the Reiter protein antigen of D'Alessandro and Dardanoni to have a high degree of specificity. However, these studies have not included leprosy patients. Therefore, this study was undertaken to determine the relative specificity and usefulness of Reiter protein antigen when employed with the serum of presumably nonsyphilitic leprosy patients. To provide serologic comparison the RPCF, TPI, TPCF, VDRL slide, and Kahn standard tests were performed in parallel on all specimens.

Methods and Material

The RPCF test was that described by Cannefax and Garson (6).

The TPCF (*Treponema pallidum* complement fixation) test was the original procedure of Portnoy and Magnuson (7).

The TPI test was that of Nelson and Diesendruck (8) with added complement according to Thompson and Magnuson (9) and increased sodium thioglycolate as recommended by Portnoy, Harris, and Olansky (10).

Table 2. Reactivity to each test of 248 leprosy patients

Test	Positive reactions	
	Number	Percent
TPI-----	12	4.8
RPCF-----	8	3.2
TPCF-----	38	15.3
VDRL-----	68	27.4
Kahn-----	89	35.9

The VDRL and Kahn tests were those described in *Serologic Tests for Syphilis, 1955 Manual (11)*, and were performed at the Public Health Service Hospital, Carville.

The RPCF, TPI, and TPCF tests were performed at the Venereal Disease Experimental Laboratory, Communicable Disease Center, Public Health Service, University of North Carolina School of Public Health, Chapel Hill.

The patients in this study were unselected in regard to previous serologic testing, age, sex, or form of leprosy. The only criterion for inclusion of patients in this study was that they not have a history or clinical evidence of syphilis.

Results

Table 1 gives the results for each of the five tests with serum specimens from 248 leprosy patients. These data are summarized in tables 2, 3, and 4.

The reactivity of the various tests with serum specimens from the 248 patients is shown in table 2. The RPCF test gave the lowest percentage of positive reactions, 3.2 percent, followed closely by the TPI test with 4.8 percent positive. The TPCF test gave 15.3 percent positive reactions. The highest percentage of positive reactions occurred with the Kahn test, 35.9 percent, with the VDRL slide test showing a somewhat smaller proportion, 27.4 percent.

Table 3 summarizes the data of table 1 to show the reactions of a given test compared with those obtained with each of the other tests.

Table 4 presents the percentage of agreement between each pair of tests, figured as the

Table 4. Percentage agreement among test results for all possible pairs of tests

Test	RPCF	TPCF	VDRL	Kahn
TPI-----	96.0	85.5	75.8	68.1
RPCF-----		87.1	74.2	65.7
TPCF-----			68.5	61.7
VDRL-----				87.5

sum of the number of serum specimens giving positive reactions to both tests and negative reactions to both tests divided by the number of serums tested. The highest agreement between any two tests, 96 percent, was between the TPI and RPCF tests. The disagreement in reaction to these two tests was in 7 serums which were TPI positive and RPCF negative and in 3 which were TPI negative and RPCF positive. Agreement between the TPI and TPCF tests was 85.5 percent. The lack of agreement was accounted for in the major part by finding 31 positive reactions to the TPCF test among serums negative to the TPI test. Comparing the reactions of the RPCF test and the TPCF test, the agreement was 87.1 percent. The percentage agreement between the reagin tests, Kahn and VDRL, and the RPCF, TPCF, and TPI tests was a much lower order. In most instances the disagreement was in the direction of more positive reactions with the reagin tests.

Discussion

This study was initiated to determine the relative specificity and usefulness of the RPCF

Table 3. Comparison between pairs of tests of test results of serum specimens from 248 leprosy patients

Test	RPCF		TPCF		VDRL		Kahn	
	Positive	Negative	Positive	Negative	Positive	Negative	Positive	Negative
TPI { Positive-----	5	7	7	5	10	2	11	1
Negative-----	3	233	31	205	58	178	78	158
RPCF { Positive-----			7	1	6	2	6	2
Negative-----			31	209	62	178	83	157
TPCF { Positive-----					14	24	16	22
Negative-----					54	156	73	137
VDRL { Positive-----							63	5
Negative-----							26	154

test when employed with the serum of leprosy patients. The data accumulated demonstrate that the RPCF test possesses a high degree of specificity when used as a serologic test for syphilis in a presumably nonsyphilitic population with leprosy. In only three instances was there a positive reaction to the RPCF test with negative reactions among the other tests. One of these serums was weakly reactive with the RPCF test and nonreactive to all other tests: 1 serum was nonreactive to 3 other tests; 1 serum was nonreactive to 1 other test. The RPCF test was reactive in 5 serums in which results of the other 4 tests were also reactive. Hence, only 2 serums reacted to the RPCF test that would not have been found reactive with at least 2 other tests.

There appeared to be no relationship between the type of leprosy, the activity of the disease, and the response to the different tests. Previous studies which have employed standard serologic tests for syphilis have generally shown an appreciable incidence of biologic false-positive results only among lepromatous cases. The patients were divided into the following categories: active lepromatous, 167; arrested lepromatous, 56; active tuberculoid, 11; and inactive tuberculoid, 14. Of the patients reactive to all tests, 4 were lepromatous in type with positive bacteriology, the remaining 1 was a negative tuberculoid. The single patient weakly reactive with the RPCF test who was negative to all other tests was a positive tuberculoid.

Summary and Conclusions

The serums of 248 presumably nonsyphilitic leprosy patients tested with five serologic tests resulted in the following reactivities: RPCF, 3.2 percent; TPI, 4.8 percent; TPCF, 15.3 percent; VDRL, 27.4 percent; and Kahn, 35.9 percent.

Comparison of the reactivities of the five tests indicates that the RPCF and TPI tests most closely approximated the expected serologic activity in relation to clinical and anamnestic information.

It appears reasonable to conclude from the data accumulated during this study that the reliability of the RPCF test with serum from

patients with leprosy is of the same order of magnitude as the TPI test and more reliable than the TPCF, VDRL, and Kahn tests.

Prevalence, incidence, and carrier rates reveal that intestinal infection is common in Alaska, especially among infants and preschool children. The greatest incidence is in the summertime.

Acute Intestinal Infection in Alaska

JOHN E. GORDON, M.D., and FRANK L. BABBOTT, JR., M.D.

THE ARCTIC is no longer the isolated, almost legendary part of the world that it once was. The military consequences of an atomic age, the press for natural resources, and the demands of international air travel bring increasing numbers of people to arctic and sub-arctic regions, with a consequent need for information on medical problems incident to life in cold climates (1).

Epidemiological investigation in the arctic has a peculiar fascination; so little has been done that almost every observation is a contribution to knowledge. This satisfaction is tempered, however, by the realities of fieldwork in a physical environment demanding beyond most others. Hotels are not to be found in the far north; even a modest lodging house is rare; and the hospitality of what may be no more than a chance acquaintance becomes priceless. Travel is arduous. Long trips by commercial airline and local travel by boat, bush plane, and dog sled to collect information on a few hundred people are not unusual. A diet that in-

cludes whale meat and seal liver, although admittedly these are delicacies, still takes some accommodating.

The intestinal infections are an attractive starting place in arctic epidemiology because the mass behavior of these diseases has been well worked out through long study in temperate and tropical regions. Also, the required bacteriological procedures are relatively simple, a consideration of moment in the arctic where field conditions are as difficult as they are. Alaska was chosen as the first study area. As a cultural and administrative part of the United States, conditions were good for communication and cooperation.

The primary purpose was to determine under arctic conditions the mode of transmission of acute infectious diarrhea of man, and to learn something of prevalence and seasonal incidence. Also, intestinal parasites of dog and man were surveyed in two villages, and the ecology of fish tapeworm was examined in one area.

Recurring outbreaks of enteric disease have been recorded among Eskimo populations of Alaska for at least a century and a half, along with dramatic epidemics of smallpox, measles, and influenza. In 1807, Unalaska was devastated by an epidemic, presumably of bacillary dysentery, and the Klondike gold rush of the late 19th century brought outbreaks of dysentery and typhoid fever (2). *Salmonella typhosa* and other salmonellae were isolated repeatedly after the first public health laboratory was established in 1936. Seventeen cases of typhoid fever occurred in Anchorage and its

Dr. Gordon is professor of preventive medicine and epidemiology, and Dr. Babbott, formerly associate in epidemiology, Harvard School of Public Health, Boston, Mass., is now assistant professor of preventive medicine and epidemiology, University of Pennsylvania Medical School, Philadelphia. This study was sponsored by the Commission on Environmental Hygiene, Armed Forces Epidemiological Board, and supported in part by the Office of the Surgeon General, Department of the Army, Washington, D. C.

vicinity in 1950 (3). Epidemics of shigellosis have been reported within the last decade in such scattered localities as Anchorage, Unalakleet, the Kuskokwim delta, and Barrow (2). Acute diarrheal disease apparently is neither a new nor a negligible cause of morbidity and mortality in Alaska although it is better defined in the south than in truly arctic territory within the Arctic Circle. Such information as exists has been derived mainly from epidemic events; the endemic behavior of enteric and other diseases is little known.

Field Method and Procedure

A choice of study plans rested between a continuous investigation in a single area over a projected period of 3 years or a series of 1-year cross-section surveys in different but representative kinds of arctic environment. The far north with its tundra, taiga, and glacial topography is as varied as the tropics. The main purpose was to define principles governing the mass behavior of intestinal disease in arctic climates. Consequently the decision was for a series of studies in three characteristic regions, the tundra terrain of Alaska, the taiga of Lapland, and the glacier country of Greenland. Similar methods were used in each, and all were under the same field direction. This report concerns Alaska.

The Alaskan studies and those which followed determined primarily the qualitative nature and prevalence of acute intestinal disorders; less certain information on incidence was derived from histories of past illness. In all three areas interest has been such that the future long-term studies necessary for detailed knowledge may be anticipated from local sources.

One Alaskan study population included the Eskimo village of Wainwright, 100 miles west of Point Barrow on the Arctic Ocean, a truly arctic region. The second included three subarctic communities, predominantly Eskimo, in the Kuskokwim delta 400 miles west of Anchorage in southwest Alaska. The intent was to identify similarities and differences in disease behavior in arctic and subarctic situations.

Alaskan residents of the interior and the north live almost wholly in small settlements or

villages, ranging from perhaps 25 inhabitants to centers of 1,000 or more, with 100 to 300 persons the usual concentration. The settlements are widely separated, oftentimes 100 miles apart. Scattered homesteads in a rural setting do not exist for the reason that there is no agriculture in arctic Alaska nor in a goodly part of the northern subarctic. Inhabitants of the villages migrate seasonally to temporary fishing camps or hunting locations on which depends the food supply for dog and man.

The terrain in all four areas was characteristically tundra, the counterpart of the tropical desert. The initial investigations were made during late summer and autumn of 1954 and winter of 1955. Both arctic and subarctic regions were observed again in late spring and early summer of 1955, the time of year when, according to local tradition, epidemics of intestinal disease are concentrated.

The field team included an epidemiologist, a bacteriologist, and an interpreter locally recruited in each village. By house-to-house visits we obtained a census of the community, data on families and family members, and information on physical and social features of the environment relating to the behavior of enteric disease. We examined patients with acute diarrhea and obtained histories of such illness for each family member during the preceding year, the criteria being three or more loose stools in a single day with variable symptoms and duration. The histories included dates of onset and time sequence within the household. Arrangements were made for stool specimens, and approximately 88 percent of the interviewed persons cooperated.

Histories of minor illness have recognized weaknesses, especially when concerned with events that occurred several months before. A good clinical description is scarcely to be expected, and the longer the interval, the less likely are illnesses to be recalled. Morbidity data on common endemic intestinal infections are almost completely lacking in these arctic regions, and they are sketchy at best for most populations anywhere. By taking an actual census of the study population and by making surveys at different seasons of the year, the frequency of diarrheal disease and the age groups most involved were reasonably estimated.

A conviction that the laboratory is an essential feature of fieldwork required full support in this instance, for it was necessary to transport 800 pounds of apparatus and materials in field chests by air either to Barrow or Bethel, and thence by multiple trips in small, chartered bush plane or river boat to the villages under study. Adequate and comfortable space was usually available in the community schoolhouse, but a laboratory in the arctic should not anticipate the usual niceties of running water, gas, and electric current.

Specimens of feces collected in the field were plated promptly on *Salmonella-Shigella* (Difeo) agar, and also inoculated into selenite enrichment broth (4). The remainder was examined for intestinal parasites. After 18 to 24 hours incubation of the enrichment medium, a second SS agar plate was made. Suspicious colonies from both sources were picked into triple sugar iron agar (5). Cultures having growth characteristics compatible with *Shigella* or *Salmonella* were transferred to nutrient agar slants. Confirmation through biochemical tests and serologic typing was done later in Anchorage at the Arctic Health Research Center, Public Health Service. Ill-defined cultures ultimately were identified at the Laboratory Branch, Communicable Disease Center, Atlanta, Ga.

In addition to providing facilities of a base laboratory, the staff of the research center and of the laboratories of the Alaska Department of Health also took part in a number of the field studies. The knowledge they had of the country and of local disease behavior was of material aid. Subsequently, Fournelle and associates continued observations in the subarctic study area, the results of which are published in this issue of *Public Health Reports* (pp. 55-59).

Incidence of Acute Diarrheal Disease

The population of the four Alaskan communities of Wainwright, Bethel, Napaskiak, and Kwethluk, as determined by actual census, was 1,197 persons, of whom 692 were interviewed by household visit. Since whole families were the unit of observation, the study group was representative of age and sex dis-

Table 1. Acute diarrhea in four Alaskan communities,¹ 1954-55, by age

Age (years)	Number of persons	Cases of diarrhea during preceding year ²	Incidence per 1,000 population per year ²	Observed cases of diarrhea ³	Prevalence per 1,000 population
0-4----	143	55	385	5	35
5-14----	203	41	202	1	5
15-44----	259	29	112	5	19

Total..	692	145	210	11	16

¹ Wainwright, Bethel, Napaskiak, and Kwethluk.

² Determined by household interviews.

³ Determined by single visit.

tributions within the village. The number of cases of diarrhea recalled for the previous 12 months was 145, an incidence of 210 per 1,000 per year (table 1). The rate is conservative. Wainwright and Bethel were sampled in late summer and autumn, Napaskiak and Kwethluk in the spring. More nearly complete information is to be expected for months immediately preceding interview.

In the late summer sample, data were collected shortly after maximum seasonal prevalence; in the spring sample, somewhat in advance of that event. Annual rates derived from the two surveys showed no material differences and both indicated a summer maximum. A July survey expectedly would give higher rates and January lower. Dispensary records in two villages, Napaskiak and Kwethluk, showed that 26 percent and 16 percent of the population, respectively, had received medication for acute intestinal disorders during the preceding year. Infants and children under 4 years of age were most commonly ill. This evidence agrees closely with the information obtained by household visit. The rate of 210 per 1,000 per year presumably expresses with fair reliability the frequency of the more severe diarrheal attacks.

The seasonal distribution of 145 recalled cases of diarrhea as obtained by household interview shows a well-marked preponderance in the summer months (table 2), nearly double the number for any other 60-day period.

vicinity in 1950 (3). Epidemics of shigellosis have been reported within the last decade in such scattered localities as Anchorage, Unalakleet, the Kuskokwim delta, and Barrow (2). Acute diarrheal disease apparently is neither a new nor a negligible cause of morbidity and mortality in Alaska although it is better defined in the south than in truly arctic territory within the Arctic Circle. Such information as exists has been derived mainly from epidemic events; the endemic behavior of enteric and other diseases is little known.

Field Method and Procedure

A choice of study plans rested between a continuous investigation in a single area over a projected period of 3 years or a series of 1-year cross-section surveys in different but representative kinds of arctic environment. The far north with its tundra, taiga, and glacial topography is as varied as the tropics. The main purpose was to define principles governing the mass behavior of intestinal disease in arctic climates. Consequently the decision was for a series of studies in three characteristic regions, the tundra terrain of Alaska, the taiga of Lapland, and the glacier country of Greenland. Similar methods were used in each, and all were under the same field direction. This report concerns Alaska.

The Alaskan studies and those which followed determined primarily the qualitative nature and prevalence of acute intestinal disorders; less certain information on incidence was derived from histories of past illness. In all three areas interest has been such that the future long-term studies necessary for detailed knowledge may be anticipated from local sources.

One Alaskan study population included the Eskimo village of Wainwright, 100 miles west of Point Barrow on the Arctic Ocean, a truly arctic region. The second included three subarctic communities, predominantly Eskimo, in the Kuskokwim delta 400 miles west of Anchorage in southwest Alaska. The intent was to identify similarities and differences in disease behavior in arctic and subarctic situations.

Alaskan residents of the interior and the north live almost wholly in small settlements or

villages, ranging from perhaps 25 inhabitants to centers of 1,000 or more, with 100 to 300 persons the usual concentration. The settlements are widely separated, oftentimes 100 miles apart. Scattered homesteads in a rural setting do not exist for the reason that there is no agriculture in arctic Alaska nor in a goodly part of the northern subarctic. Inhabitants of the villages migrate seasonally to temporary fishing camps or hunting locations on which depends the food supply for dog and man.

The terrain in all four areas was characteristically tundra, the counterpart of the tropical desert. The initial investigations were made during late summer and autumn of 1954 and winter of 1955. Both arctic and subarctic regions were observed again in late spring and early summer of 1955, the time of year when, according to local tradition, epidemics of intestinal disease are concentrated.

The field team included an epidemiologist, a bacteriologist, and an interpreter locally recruited in each village. By house-to-house visits we obtained a census of the community, data on families and family members, and information on physical and social features of the environment relating to the behavior of enteric disease. We examined patients with acute diarrhea and obtained histories of such illness for each family member during the preceding year, the criteria being three or more loose stools in a single day with variable symptoms and duration. The histories included dates of onset and time sequence within the household. Arrangements were made for stool specimens, and approximately 88 percent of the interviewed persons cooperated.

Histories of minor illness have recognized weaknesses, especially when concerned with events that occurred several months before. A good clinical description is scarcely to be expected, and the longer the interval, the less likely are illnesses to be recalled. Morbidity data on common endemic intestinal infections are almost completely lacking in these arctic regions, and they are sketchy at best for most populations anywhere. By taking an actual census of the study population and by making surveys at different seasons of the year, the frequency of diarrheal disease and the age groups most involved were reasonably estimated.

human and dog feces, to give a relatively high community dosage but no clinical cases in man.

Epidemic Studies

Promptly with breakup of winter ice in the Kuskokwim River and the opening of navigation in May 1955, headquarters were set up in the village of Napaskiak to investigate in delta communities the anticipated epidemics of diarrheal disease reportedly associated with the spring thaw. The first clinical illness did not appear until mid-June. In nearby Oscarville, a small settlement with unusually poor living conditions, 5 active cases were identified in a population of 48 over a period of 3 weeks, and 4 other persons gave a history of diarrhea within the preceding 2 weeks. *S. flexneri* 2a was isolated from a sick child and from 2 sibling contacts, and *S. flexneri* 3 from an elderly man and his 5-year-old granddaughter, both clinically ill.

Casefinding investigations included 13 other settlements and salmon fishing camps scattered along 20 miles of river and the coastal village of Wainwright bordering on the Arctic Ocean where breakup occurs much later. In a population of 1,050 people observed for 6 weeks after breakup, 21 clinical cases of diarrhea were seen, and a history of 25 other recent illnesses was elicited. Fournelle and his associates resurveyed the Kuskokwim delta area that same autumn and again in late 1956. His reported results in this issue of *Public Health Reports* give details of his earlier communication to us: that in both years more than a quarter of the persons in the area had had diarrhea in the preceding warm weather months; *S. flexneri* 2a was isolated from carriers and patients, two-thirds of whom were less than 12 years old.

Bacillary dysentery, therefore, is endemic in the Kuskokwim area. The reputed occurrence of epidemics associated with breakup did not materialize. Rather, there was a slow buildup of cases, reaching a maximum morbidity in midsummer. Sporadic infections or family groupings of cases are the rule, although small outbreaks occur and *S. flexneri* is as regularly isolated in such instances as in endemic diarrheal disease. Infants and children are most commonly affected.

Conditions in the arctic community of Wainwright essentially duplicated those observed in the subarctic Kuskokwim in incidence, prevalence, and carrier rates, with shigellae again so much the predominating infectious agent that independent tabulations were not necessary.

Mode of Transmission

Acute intestinal disease in the arctic certainly originates in contaminated food or water. A classic outbreak of staphylococcal food poisoning affecting 12 of 35 persons in a camp of state-side workers was an incidental experience in the course of the studies of Eskimo populations. The walrus epidemic of trichinosis in Greenland (8) in 1948 was outstandingly a foodborne infection. The early history of enteric infection in Alaska contains repeated reference to waterborne typhoid fever, and such outbreaks still continue (2). The sanitary precautions accorded whale and caribou meat are such as to suggest to the outsider a distinct likelihood of intestinal infection. Family outbreaks may occur, but there is no record of a community epidemic from such sources.

The annual summer outbreaks of diarrhea are believed largely due to person-to-person contact. The evidence is fourfold. In the first place, cases in a population tend to occur sporadically as opposed to the multiple primary cases of a common-source epidemic with transmission by vehicle. Second, outbreaks are characteristically of slow evolution and protracted course, unlike the sharp-point epidemic related to contaminated community food or water supply. During our investigation, summer outbreaks occurred but not in proximity to the spring thaw and the breakup of ice in rivers and ocean, by which the accumulated wastes of the winter presumably are washed into surface waters. The first cases came some weeks later, and numbers built up gradually to reach a peak in midsummer. Some infections and particularly the earlier ones may well have originated in contaminated water, but the propagation and subsequent course was that of contact spread.

In the third place, food habits of the Eskimo villagers preclude common vehicle transmission since each family is largely responsible for procuring and preparing its own food and

Again, because of the time that surveys were made, a seasonal variation with most cases in early summer appears established; autumn and spring may be unduly weighted.

Because of deficiencies in memory of past minor medical events, these numbers certainly do not represent all cases of acute diarrhea during the year. Based on prevalence (table 1) and a duration of 5 days, the expected incidence is in excess of 1,150 per 1,000 per year.

Prevalence of Acute Diarrheal Disease

Eleven cases of acute diarrhea were encountered in this general population in the course of single household visits, to give a prevalence of 16 per 1,000 population (table 1). *Shigellae* were isolated from three. The frequency was greatest among children under 4 years of age, which coincides with the high incidence in this group as determined by histories of past illnesses. Next in rank was the age group 15-44 years, where little illness was recalled during the previous year. The small numbers permit no conclusions; they do suggest that diarrhea occurs more frequently in this middle-age range than was remembered or reported in the retrospective study of incidence.

Carrier Rates

Identification of shigellae or salmonellae in stools of healthy persons ranged from 0 in Napaskiak to 5 percent in Bethel (table 3). De-

Table 3. Carriers of *Shigella* and *Salmonella* in four Alaskan communities, 1954-55; rates per 100 healthy persons examined

Community	Population	Number examined	Number of carriers		Total percent carriers
			<i>Shigella</i>	<i>Salmonella</i>	
Wainwright--	230	188	6	0	3.2
Bethel-----	600	138	3	4	5.1
Napaskiak----	130	115	0	0	0
Kwethluk----	237	129	1	3	3.1
Total---	1,197	570	10	7	3.0

spite failure to identify a carrier in Napaskiak, that community reported the highest annual incidence of acute diarrheal disease, 280 per 1,000, of any of the four communities. Only 2 of 17 carriers were adults, both from Kwethluk and both harboring *S. typhosa* of the phage type responsible for the 1950 epidemic in that village. Two carriers were adolescents; the remaining 13 were 12 years of age or less. Age distributions of persons examined are proportionately those of table 1, from which population they were drawn; the numbers differ because some people failed to supply specimens and others with clinical diarrhea were excluded. The low carrier rates for *Shigella* in Napaskiak and Kwethluk may well have been due to the time of year these communities were sampled, in late March and April and 7 to 8 months after the usual peak of summer diarrhea. A prolonged carrier state for *Shigella* is unusual. On the other hand, the results from Wainwright and Bethel were from the autumn survey, much closer to the epidemic season.

Of organisms isolated from carriers, 5 of the 10 shigellae were *S. flexneri* 2a, 3 were *S. flexneri* group form variant, 1 was *S. flexneri* 3, and 1, *S. sonnei*. Of the 7 salmonellae, 4 were *S. typhosa*, and 1 each, *S. typhimurium*, *S. infantis*, and *S. oranienburg*.

No pathogens were isolated from 54 specimens of dog feces which were examined because of the possible role of dogs as a reservoir of salmonellae. Salmonellae were also absent from 300 specimens of human feces collected in the same two villages. Other studies at Barrow (6, 7) revealed *S. typhimurium* in both

Although approximately one-half of the Eskimos observed in this study gave a history of diarrhea, few pathogenic bacteria or parasites were identified as likely causative agents. While diarrhea continues to be a problem, it does not appear to be as serious today as it was in the past.

Seasonal Study of Enteric Infections in Alaskan Eskimos

H. J. FOURNELLE, Ph.D., VIRGINIA RADER, B.A., and CLARISSA ALLEN, R.N.

SEVERAL QUESTIONS pertaining to the recurrence of diarrhea and of bacterial and parasitic infections remained unanswered after a survey of enteric infections in Alaskan Eskimos (1). To augment the survey, we undertook a year's study in an Eskimo community during which time samplings were taken at different seasons. The year-long study was designed to determine occurrence of diarrhea and specific bacterial and parasitic infections by season, age, and sex, and to answer specific questions such as how many times during the year an individual reported diarrhea and how many times bacterial pathogens and parasites were found in that individual.

The occurrence of diarrhea among Alaskan natives has been reviewed by Babbott and associates (2). Fournelle and co-workers (1) found that *Shigella* was the main causative agent among the Eskimos of southwestern Alaska, where the children under 10 years of

age accounted for about two-thirds of the cases of diarrhea and isolates of bacterial pathogens. Approximately one-third of the persons surveyed reported diarrhea, with prevalence greatest during July and August. Few *Salmonella typhosa* and pathogenic *Escherichia coli* were isolated. Dogs were not considered important as a source of human infection because examination of 278 dogs yielded only one bacterial pathogen. Parasitic infections were not considered extensive.

Mainly because of their accessibility throughout most of the year, the neighboring villages of Napaskiak and Oscarville were selected for this seasonal study of enteric infections. The villages are located on the Kuskokwim River in southwestern Alaska about 5 miles from Bethel and approximately 400 air miles from Anchorage. Napaskiak's population was 129 and Oscarville's 46, with a total of 38 household units.

A house rented from an Eskimo in Napaskiak served as a bacteriological field laboratory and as living quarters for the fieldworker (Fournelle). Procedures and techniques have been described previously (3). Briefly, fecal specimens were cultured on SS agar, with enrichment in selenite broth in most cases. Colonies resembling salmonellae, shigellae, or coliform organisms (in infantile diarrhea) were picked onto TSI agar slants and were saved for further

Dr. Fournelle is chief, and Mrs. Allen, an assistant, Bacteriology Unit, Arctic Health Research Center, Public Health Service, Anchorage, Alaska. Mrs. Rader, Gulfport, Miss., was employed under contract as parasitologist. Dr. R. N. Philip, also with the Center, assisted in the preparation of this paper. A portion of the paper was read at the 8th Alaskan Science Conference in Anchorage, September 10-13, 1957.

drink. Finally, the *Shigella* group of enteric pathogens predominated in carrier surveys and among infectious agents isolated from patients. Shigellosis is notably spread by person-to-person contact, although of course vehicle transmission occurs.

Summary

Field studies in 4 Eskimo villages of Alaska, 1 on the arctic coast and 3 in the subarctic Kuskokwim delta region, demonstrated acute diarrheal disease to be common, especially among infants and preschool children. Incidence was greatest in summer. A variety of pathogenic bacteria were isolated from cases and carriers, with *Shigella flexneri* 2a and 3 in greatest frequency. Transmission of intestinal infection in sporadic cases, in family groupings, and in small outbreaks was mainly by person-to-person contact.

New Clinical Neuropsychopharmacology Research Center

A comprehensive study of drugs and their use in the treatment of mental illness will be conducted at a clinical neuropsychopharmacology research center recently established at St. Elizabeths Hospital. The Federal mental hospital and the National Institute of Mental Health have joined forces in the project.

St. Elizabeths, with its 7,500 patients, provides an ideal setting for clinical studies. The building selected for the center houses 350 patients and is being equipped with laboratories and other facilities for basic research.

At the center, psychiatrists, psychologists, pharmacologists, biochemists, physiologists, and other specialists will conduct extensive studies to determine what happens, physically and psychologically, when tranquilizing and energizing drugs are used in the treatment of various types of mental disorder.

The project will also include research designed to measure the changes in hospital management and care brought about by the use of drugs and how such environmental changes affect the patient.

Dr. Joel J. Elkes, a National Institute of Mental Health pharmacologist and former chairman of the department of experimental psychiatry at the University of Birmingham in England, is the center's director.

The organism was isolated during the August field trip from a 16-year-old male and from an elderly woman whose age was not ascertained. The third individual was a 4-month-old girl from whom the organism was isolated during the January trip.

Parasitic Infections

Parasitological examinations were also made of the 638 fecal specimens collected during the year. All specimens were examined by the MIF direct (4) and concentration techniques (5). There were 292 (45.8 percent) specimens positive for parasites. Parasitic infection rates for the 6 sampling periods ranged between 368 per 1,000 (October) and 587 per 1,000 (April). The largest number of parasitic types found in a single specimen was three. The numbers of individuals infected with one or more parasites and those infected with *Entamoeba histolytica* and *Diphyllobothrium* sp. are shown in table 3 according to age group. In general, total parasitism was high among all age groups, with the lowest frequency of infection in those under 1 year of age. Prevalence of the three classes of parasites listed was high.

The results of the parasitological examinations are shown in table 4. Two hundred fifty-nine parasites were recovered from 174 individuals sampled. Of these, 78 (44.7 percent) had more than 1 parasite. The largest number

Table 4. Parasites recovered from preserved fecal specimens of 174 persons, July 1956-June 1957

Parasites	Number	Percent
<i>Entamoeba coli</i>	90	51.7
<i>Entamoeba histolytica</i>	15	8.6

<i>Enterobius vermicularis</i>	8	4.6
<i>Ascaris</i> sp.....	1	.6

of parasitic types found in an individual was 5, all being found in 2 girls, aged 3 and 10 years. The parasites were *Entamoeba coli*, *Endolimax nana*, *Iodamoeba buetschlii*, *Diphyllobothrium* sp., *E. histolytica*, or *Giardia lamblia*. The 2 girls submitted 5 and 4 specimens, respectively, in each of which 1 or more parasites were found.

Ten of the 15 individuals positive for *E. histolytica* were found in the July sampling. One of the 15 was positive twice, in July and October.

Forty-four (73.3 percent) of the 60 individuals positive for *Diphyllobothrium* sp. were found in the April sampling. Eight individuals were positive twice (7 of them in consecutive samplings), and 1 each was positive 3, 5, and 6 times. One woman, aged 40, was positive

studies in the Anchorage laboratory. For the parasitological examination, a small portion of the fecal specimen was placed in MIF stain-preservative solution (4), which was later shipped to Mississippi for examination by a contract parasitologist.

Prior to laboratory work, each occupied dwelling in the two villages was visited to find out something about morbidity from diarrhea among members of the households. Since it was necessary to employ an interpreter during the interview, diarrhea was defined simply as consisting of at least 3 or 4 stools a day and usually lasting at least 3 days. Although we sought additional information on symptoms, we were not always successful. Usually the mother was the informant. Specimen cartons were left for everyone with instructions to bring specimens to the field laboratory soon after they were passed.

Findings

Six field trips were made during July 1956 to June 1957 with samplings and examinations during July, August, October, January, April,

and June. The individuals sampled in each of the 6 interviews numbered 146, 163, 135, 167, 167, and 147, and totaled 925. Diarrheal attack rates, by month of occurrence, are shown in table 1. Where history of diarrhea was reported, a single episode was recorded only once, although it may have been reported more than once during successive interviews.

The total cases of diarrhea reported were 163. The annual diarrheal attack rate for the community was 845 per 1,000 persons observed. Eighty-eight (50.6 percent) of the 174 individuals sampled reported diarrhea during the year. Of the persons who reported diarrhea, 38 (43.2 percent) had 1 diarrheal attack; 30 (34.1 percent) had 2 attacks; 15 (17.0 percent) had 3 attacks; and 5 (5.7 percent) had 4 attacks. Frequency of diarrhea appeared to be greater among females (53/94) than among males (35/80), but the difference is not statistically significant ($P=0.10$). Annual diarrheal attack rates, according to age groups, are shown in table 2.

Bacterial Pathogens

Bacteriological examinations were made of 638 fecal specimens collected during the six sampling periods. In most instances, multiple stool specimens were received from the 174 individuals sampled, with an average of 3.7 specimens per individual. Only 1 bacterial pathogen, *Shigella flexneri* 2a, was isolated from 3 individuals who gave no history of diarrhea.

diarrhea. In view of this, it is difficult to consider the parasites of any importance as possible causative agents of diarrhea. Of the 15 individuals positive for *E. histolytica*, 9 reported no diarrhea whatsoever throughout the year; 5 reported no diarrhea at the time the specimen was taken; and only 1 person reported diarrhea when the specimen was taken. We have no idea why the highest infection rate for *E. histolytica* occurred during the July sampling nor why the highest *Diphylllobothrium* sp. rate occurred during the April sampling. According to R. L. Rausch in a personal communication, certain of the fish used as food by these people are infected with several species of *Diphylllobothrium*, none of which has been identified as *D. latum*.

The MIF technique of stool preservation has been found to be well suited to delayed examination. Examination by both the direct and concentration procedures gave a greater recovery of parasites than one procedure alone.

Summary

Eighty-eight (50.6 percent) of the 174 Eskimos observed in the villages of Napaskiak and Oscarville during a 1-year period gave a history of diarrhea at some time during the course of the study. Most cases were reported during July and August. Children under 10 years of age accounted for 62.0 percent of the cases of diarrhea, and gave an annual attack rate of 1,431 per 1,000 persons observed. One

bacterial pathogen, *Shigella flexneri* 2a, was isolated from three individuals.

Parasitic infections were high among all age groups, with an average of 77.0 percent of the people parasitized. *Entamoeba coli*, *Endolimax nana*, and *Diphylllobothrium* sp. were most numerous. Individual infection rates for *Entamoeba histolytica* and *Diphylllobothrium* sp. were 8.6 and 34.5 percent, respectively. There appeared to be no correlation between parasitic infection rates and the occurrence of diarrhea.

Research, Construction, and Training Grants

During the fiscal year ending in June 1958, the National Institutes of Health, Public Health Service, awarded 9,534 grants totaling \$136,112,014 for research, training, and construction in non-Federal institutions.

Details of the 1958 operations are given in the publication, *Public Health Service Grants and Fellowships Awarded by the National Institutes of Health, 1958*.

More than two-thirds of the total grant funds were allotted to 7,028 research projects concerned with the major diseases and other aspects of the medical and biological sciences, in 699 institutions in the United States and 28 foreign countries. Grants to help build, equip, or expand 177 research facilities were made on a matching basis to 134 institutions throughout the Nation, and research fellowships were awarded to 2,329 fellows.

3 times; a man, aged 49, 5 times; and a 7-year-old girl, 6 times.

Discussion

This study has revealed a number of points which are similar to the results of the survey previously reported (1). The diarrheal morbidity rate was highest in the age group under 10 years, which also accounted for the largest number of cases of diarrhea. Since interviewing was more frequent during the summer months, more cases of diarrhea were reported during July and August. Although only 1 bacterial pathogen was isolated, it was 1 of the 2 found most often during the survey. There were fewer parasitic infections in younger age groups. The same three parasites were found most often, *E. coli*, *E. nana*, and *Diphyllobothrium* sp.

The number of reported cases of diarrhea varied considerably during the seasonal interviews; high and low attack rates were found during both summer and winter. While most cases of diarrhea were reported as occurring during the summer, there also appeared to be an upsurge in December and January. Diarrhea was reported an average of 1.9 times by the 88 individuals who gave a history of diarrhea, and of these, 50 (56.8 percent) gave a positive history either 2, 3, or 4 times. Certain parasites recurred in the stools of some individuals. These recurrences were either reinfections or continued carrier status, or a combination of both. It was mentioned earlier that *Diphyllobothrium* sp. was found 3, 5, and 6 times in stool specimens taken from 3 individuals during the 6 sampling periods. As would be expected, the largest numbers of repeated positive stools per individual, either in consecutive or intermittent samples, were for *E. coli* and *E. nana*. *E. coli* was found in 3 individuals on 4 consecutive samplings and in 7 and 19 on 3 and 2 consecutive samplings, respectively. *E. nana* was found in 1 and 10 individuals on 3 and 2 consecutive samplings, respectively. These parasites were also found 2 or 3 times in a number of other persons but on intermittent samplings. In most parasitized individuals, these parasites were found only once, for example, *E. coli* in 41 individuals and

E. nana in 49. Most of the other parasites were found only once in a person during the entire year.

No sharp enteric outbreak was reported during the year, although high attack rates were noted during several of the interviews. Although there was a midwinter increase in the number of reported cases of diarrhea, approximately one-half of all cases (51.7 percent) were reported during the period from June to September. Occurrence of the illness was reported as sporadic within and among the families of the two villages.

During interviewing, the symptoms of reported diarrhea appeared to be mild. This was confirmed by Fournelle who experienced a mild diarrheal attack while in the village during the August field trip. (*S. flexneri* 2a was isolated from several fluid stool specimens.)

During the survey prior to this study an impression was obtained that diarrheal diseases were not as serious at that time as had been reported in past years. We wonder now if the problem is even less serious in the community where this study was made in view of the lower attack rates and fewer isolated bacterial pathogens. In general, the community exhibited a higher degree of sanitation, as reflected by personal and household cleanliness, than was shown in most villages visited during the preceding survey.

Although the bacteriological findings of this study are meager and give few clues to the cause of the reported incidence of diarrhea, the survey revealed that the main source was *Shigella*, including, among several organisms, *S. flexneri* 2a, which was isolated in this study. Shigellosis was also implicated in the present study by the sporadic nature of the attacks and by the involvement principally of the group under 10 years of age.

In some instances our findings for parasites varied considerably from the results of Hitchcock (6). Our results are based on specimens collected during a 1-year period, while Hitchcock's were based on specimens taken in a few days. The low *Enterobius vermicularis* rate we found is no doubt due to the examination of the passed stool specimen.

There appeared to be no correlation between parasitic infection rates and the occurrence of

diarrhea. In view of this, it is difficult to consider the parasites of any importance as possible causative agents of diarrhea. Of the 15 individuals positive for *E. histolytica*, 9 reported no diarrhea whatsoever throughout the year; 5 reported no diarrhea at the time the specimen was taken; and only 1 person reported diarrhea when the specimen was taken. We have no idea why the highest infection rate for *E. histolytica* occurred during the July sampling nor why the highest *Diphylllobothrium* sp. rate occurred during the April sampling. According to R. L. Rausch in a personal communication, certain of the fish used as food by these people are infected with several species of *Diphylllobothrium*, none of which has been identified as *D. latum*.

The MIF technique of stool preservation has been found to be well suited to delayed examination. Examination by both the direct and concentration procedures gave a greater recovery of parasites than one procedure alone.

Children under 10 years of age accounted for 62.0 percent of the cases of diarrhea, and gave an annual attack rate of 1,431 per 1,000 persons observed. One

bacterial pathogen, *Shigella flexneri* 2a, was isolated from three individuals.

Parasitic infections were high among all age groups, with an average of 77.0 percent of the people parasitized. *Entamoeba coli*, *Endolimax nana*, and *Diphylllobothrium* sp. were most numerous. Individual infection rates for *Entamoeba histolytica* and *Diphylllobothrium* sp. were 8.6 and 34.5 percent, respectively. There appeared to be no correlation between parasitic infection rates and the occurrence of diarrhea.

Research, Construction, and Training Grants

During the fiscal year ending in June 1958, the National Institutes of Health, Public Health Service, awarded 9,534 grants totaling \$136,112,014 for research, training, and construction in non-Federal institutions.

Details of the 1958 operations are given in the publication, *Public Health Service Grants and Fellowships Awarded by the National Institutes of Health, 1958*.

More than two-thirds of the total grant funds were allotted to 7,028 research projects concerned with the major diseases and other aspects of the medical and biological sciences, in 699 institutions in the United States and 28 foreign countries. Grants to help build, equip, or expand 177 research facilities were made on a matching basis to 134 institutions throughout the Nation, and research fellowships were awarded to 2,329 fellows.

diarrhea. In view of this, it is difficult to consider the parasites of any importance as possible causative agents of diarrhea. Of the 15 individuals positive for *E. histolytica*, 9 reported no diarrhea whatsoever throughout the year; 5 reported no diarrhea at the time the specimen was taken; and only 1 person reported diarrhea when the specimen was taken. We have no idea why the highest infection rate for *E. histolytica* occurred during the July sampling nor why the highest *Diphylllobothrium* sp. rate occurred during the April sampling. According to R. L. Rausch in a personal communication, certain of the fish used as food by these people are infected with several species of *Diphylllobothrium*, none of which has been identified as *D. latum*.

The MIF technique of stool preservation has been found to be well suited to delayed examination. Examination by both the direct and concentration procedures gave a greater recovery of parasites than one procedure alone.

Summary

Eighty-eight (50.6 percent) of the 174 Eskimos observed in the villages of Napaskiak and Oscarville during a 1-year period gave a history of diarrhea at some time during the course of the study. Most cases were reported during July and August. Children under 10 years of age accounted for 62.0 percent of the cases of diarrhea, and gave an annual attack rate of 1,431 per 1,000 persons observed. One

bacterial pathogen, *Shigella flexneri* 2a, was isolated from three individuals.

Parasitic infections were high among all age groups, with an average of 77.0 percent of the people parasitized. *Entamoeba coli*, *Endolimax nana*, and *Diphylllobothrium* sp. were most numerous. Individual infection rates for *Entamoeba histolytica* and *Diphylllobothrium* sp. were 8.6 and 34.5 percent, respectively. There appeared to be no correlation between parasitic infection rates and the occurrence of diarrhea.

Detecting Poliovirus in Vaccine Lots Used in Idaho in 1955

CARL M. EKLUND, M.D., WILLIAM J. HADLOW, D.V.M., EDGAR G. PICKENS, and
ROBERT K. GERLOFF, M.A.

THE TWO LOTS of poliomyelitis vaccine associated with the outbreak of paralytic poliomyelitis among Idaho children in 1955 (1) were studied in monkeys to detect virus and compare the relative sensitivity of monkey and man. The method for isolation of poliovirus from monkeys consisted of direct injection of vaccine into those tissues of cortisone-treated animals which were known to support virus growth (2, 3). Vaccine treated with merthiolate and that treated with merthiolate and verseque were tested in order to determine the effect of these agents on residual virus.

The data reported in this paper show that the addition of merthiolate to vaccine increases the incidence of animals yielding poliovirus. The data also indicate that monkeys are approximately 500 times more susceptible than man to infection with this agent.

Methods

The monkeys were anesthetized with intravenous sodium pentobarbital before inoculation. Six milliliters of vaccine were injected into each monkey in approximately the following amounts: 0.5 ml. into each thalamic region, 0.6 ml. in the lumbar region of the spinal cord, 0.25 ml. in the region of each tonsil, 1.0 ml. in the brown fat of each axillary region, 0.25 ml. in the region of the inguinal nodes on each side, and 0.5 ml. in the muscles of each thigh.

A special 1 $\frac{1}{4}$ -inch, 25-gauge needle was used for intraspinal inoculation. The tip was blocked and a small hole was drilled through the shaft about one-eighth inch from the occluded

end. The needle was inserted approximately three-fourths inch into 1 of the first 3 lumbar interspaces so that the inoculum was directed into the long axis of the cord. If a general contraction of one leg occurred immediately after the beginning of injection, followed by a general seizure of both hind legs and the back muscles, the inoculation was considered successful; if such seizure did not occur, inoculation was attempted in one of the other interspaces. Some degree of paralysis, usually severe, always followed inoculation, but this did not interfere with the detection of subsequent paralysis caused by poliovirus infection.

All monkeys received large amounts of cortisone intramuscularly, usually 125 mg. at the time of inoculation, 50 mg. on the second, third, and fourth days after inoculation, and then 50 mg. every other day through the 14th day if the monkeys tolerated these amounts, which they usually did. Starting on the fourth day, blood for detection of virus was taken every other day through the 14th day.

Dr. Eklund, Mr. Pickens, and Mr. Gerloff are with the Rocky Mountain Laboratory, National Institute of Allergy and Infectious Diseases, Public Health Service, Hamilton, Mont., as was Dr. Hadlow before his resignation. Dr. Eklund serves as medical director in the Insect and Animal Borne Disease Section, Mr. Pickens as biological production technician in the Community Health Section, and Mr. Gerloff as sanitarian in the Pathology and Serology Section, where Dr. Hadlow was a veterinarian. Dr. Hadlow is now with the Agricultural Research Council, Compton, Berkshire, England.

Monkeys with clinical evidence of involvement in all four limbs, either paralysis or weakness, were killed by exsanguination under intravenous sodium pentobarbital anesthesia. Monkeys showing no paralysis were sacrificed similarly between the 18th and 21st days after inoculation. From all monkeys, the tonsils, deep retropharyngeal lymph nodes, axillary brown fat, axillary, inguinal, and abdominal lymph nodes, and portions of the cervical and lumbar cord were removed with sterile instruments for attempted virus isolation. The central nervous system was subjected to thorough histological examination.

In the isolation technique, essentially the same as previously reported from the Rocky Mountain and other laboratories, monkey kidney cells were used in all attempted isolations, and, in most instances, KB carcinoma cells were used in parallel tests (4). The monkey kidney cells were incubated approximately 7 days to produce confluent monolayers of cells before inoculation, and the KB carcinoma cells, about 3 days to produce small islands of confluent cells. All cultures were made in 2-oz. prescription bottles containing 10 ml. of medium.

Ten percent suspensions of organs in tissue-culture medium were employed as inoculums. These varied in toxicity to the tissue-culture

from cells, replaced with about 3 percent brown-fat suspension, and incubated at 37° C. for 4 to 5 hours. After the cells had thus been exposed to the suspension of brown fat, the suspension was removed and replaced with tissue-culture medium.

Lot 6039 was examined first; it served to determine tissues of value in detecting virus. As shown in table 1, type 1 poliovirus was isolated from tissues of 11 of 40 rhesus monkeys (*Macaca mulatta*). Virus was detected in blood, axillary brown fat, and spinal cord. Since no single tissue yielded virus consistently, all three had to be examined for maximum sensitivity in detecting type 1 virus.

Ten African green monkeys (*Cercopithecus aethiops*) were used on one occasion. Type 1 virus was not isolated although it was detected in 3 of 10 rhesus monkeys inoculated the same day. On one of the occasions when 7 cynomolgus monkeys (*Macaca philippinensis*) were used, type 1 virus was isolated from the blood, brown fat, lymphoid tissue, and spinal cord of 1 and from the blood of another.

Type 2 virus was found in the brown fat of 2 of the 40 rhesus monkeys previously mentioned and in the spinal cord of 2 others (table 2). Type 2 virus was also isolated from the spinal cord, brown fat, and lymphoid tissue of 3 of 10 green monkeys. Of the 7 cynomolgus monkeys, 1 had type 2 poliovirus in brown fat and another in the spinal cord.

Type 3 poliovirus was isolated only from the spinal cord of 1 of the 40 rhesus monkeys and not from any other tissue (table 3). It was not isolated from the green monkeys but was isolated from the spinal cords of 2 of the 7 cynomolgus monkeys.

All cultures were observed for at least 7 days after inoculation for cytopathogenic changes in the cells and passaged once on the original host cell regardless of findings in primary culture.

Antibody response was measured by a metabolic inhibition type of neutralization test similar to one described by Salk and associates (5). Trypsinized monkey kidney cells were prepared by a method closely resembling that of Rappaport (6). The highest point of serum dilution which sufficiently protected monkey kidney cells against 100 to 300 TCID₅₀ of virus to allow the pH to decrease to 7 or below was considered the antibody titer of that

Table 4. Distribution of type 1 poliovirus in monkeys inoculated with vaccine lot 6058 treated with merthiolate or merthiolate plus versene

Table 5. Distribution of type 2 and type 3 polio-virus in monkeys inoculated with vaccine lot 6058 treated with merthiolate or merthiolate plus versene

Vaccine	Total isolations from non-nervous tissue		Cord	
	Type 2	Type 3	Type 2	Type 3
Merthiolate treated	0	0	1/11	0/11
Untreated	0	0	1/10	0/10
Merthiolate plus versene treated	0	0	0/9	1/9
Untreated	0	0	0/10	1/10

NOTE: In fractions, the denominator shows the number of monkeys inoculated, and the numerator, the number having the designated poliovirus.

serum. Tests of serums collected early in the study were performed in glass tubes; those collected later were tested in cups of disposable plastic panels sterilized by ultraviolet irradiation (?). Nutrient fluid consisted of Hanks' balanced salt solution containing 0.5 percent lactalbumin hydrolysate and 2 percent horse serum. The mixture of serum, virus, cells, and nutrient fluid in each cup of the panel was overlaid with an equal quantity of mineral oil. Each panel was then covered with a sheet of sterile aluminum foil and incubated at 36° C. for 10 to 12 days as determined by behavior of the controls.

Results

Paralytic poliomyelitis from inoculation of the vaccines was limited virtually to monkeys that had a convulsive seizure at the time of inoculation. Of the 20 monkeys that had no seizure, 1, or 5 percent, had typical clinical and microscopic findings compared with 21, or 40 percent, of the 52 with convulsive seizures.

On 4 occasions, 2 different types of virus were isolated from a single rhesus monkey. Twice type 1 virus was isolated from the spinal cord in the same instances that type 2 was isolated from brown fat. Once type 2 virus was isolated from the spinal cord and type 1 from brown fat. In the final instance type 3 virus was isolated from the spinal cord and type 2 from brown fat of a cynomolgus monkey.

Neuropathological findings in two African green monkeys were typical of acute poliomyelitis although virus was not isolated from the spinal cord. In one monkey, paralysis appeared first in the legs and then extended to the arms. The resulting clinical picture was considered typical of poliomyelitis. In the other monkey, general weakness and coarse tremors were observed, but definite paralysis did not occur. In this instance type 2 virus was isolated from brown fat and mesenteric lymph nodes. The interpretation of these lesions is difficult. It may be, however, that since the distribution and character of lesions were typical of poliomyelitis, a true poliovirus infection of the central nervous system can occur in this species although virus cannot be isolated by tissue culture methods.

Effect of Merthiolate in Vaccine

Merthiolate was added to lot 6058 to determine whether it would inactivate residual poliovirus, and this treated preparation was tested only in rhesus monkeys. One aliquot of vaccine was treated with merthiolate to a final concentration of 1:10,000 and stored at 4° C. for 2 months. Another aliquot of vaccine was similarly treated with merthiolate to a final concentration of 1:10,000, and, in addition, versene was added to a final concentration of 7:10,000 in an attempt to prevent the merthiolate action on the virus. This aliquot was also stored at 4° C. for 2 months.

Table 6. Antibody response of monkeys 21 days after inoculation of vaccine lot 6058 treated with merthiolate or merthiolate plus versene

Vaccine	Type 1 response	Type 2 response	Type 3 response
Merthiolate treated	1 1/6	1/6	1/6
Untreated	1/10	10/10	1/10
Merthiolate plus versene treated	1 1/8	5/8	2/8
Untreated	1/10	10/10	3/10

¹ Monkeys who became paralyzed were generally sacrificed before the appearance of antibodies and are not included in this table.

NOTE: In fractions, the denominator shows the number of monkeys inoculated, the numerator, the number with the designated response

The merthiolate-treated portion of the vaccine was inoculated into 11 monkeys and an untreated portion into 10 control monkeys. The following day 9 monkeys were inoculated with vaccine treated with merthiolate plus versene, and again, 10 controls were inoculated with untreated vaccine.

Type 1 virus was isolated from 4 of the 11 monkeys that had received vaccine treated with merthiolate (table 4); 10 isolations were made from peripheral tissue and 3 from the spinal cord. In contrast, from the 10 control monkeys, type 1 virus was isolated only once, from brown fat. Also, in monkeys that received vaccine treated with merthiolate plus versene, type 1 virus was isolated from 4 of 9 monkeys; 6 isolations were made from non-nervous tissue and none from nervous tissue. In the control group, type 1 virus was isolated from 3 monkeys, twice from peripheral non-nervous tissue and once from spinal cord. With respect to the presence of type 2 and type 3 polioviruses, all groups were essentially the same (table 5).

Among the monkeys inoculated with lot 6058, two types of virus were isolated from the same monkey on three occasions. Type 3 was isolated from the spinal cord of two monkeys, while type 1 was isolated from brown fat of one, and type 2 from the brown fat of the other. Type 2 was isolated from the spinal cord and type 1 from brown fat of one monkey.

The antibody responses of the four groups of monkeys receiving vaccine lot 6058 possibly explain the effect of merthiolate in aiding the detection of type 1 poliovirus. Inoculation of lot 6039 in rhesus monkeys uniformly produced type 2 antibodies usually in a titer of 1:64 or higher; type 1 or 3 antibodies seldom

Table 8. Incidence of paralytic disease following inoculation of lot 6039, among animals with a successful intraspinal inoculation

Rhesus ² -----	5	3	{Type 3 from 2.
			{Type 1 from 2.
			{Type 3 from 1.

¹ Type 1 virus was also isolated from brown fat of 1 of the paralyzed monkeys and from the blood of a monkey with no clinical or microscopic findings.

² Type 1 virus was also isolated from the blood of a monkey with no clinical or microscopic findings.

appeared. With untreated vaccine of lot 6058, a similar antibody response was noted in the two groups of monkeys, but the group receiving merthiolate-treated vaccine had no type 2 antibody response (tables 6 and 7), and the group receiving vaccine treated with merthiolate plus versene had a poor type 2 antibody response. Apparently, merthiolate destroyed the antigenicity of type 2 virus and removed some component which interfered with proliferation of type 1 virus in non-neural tissues.

Estimate of Paralytic Dose

Inoculation of monkeys with poliomyelitis vaccine to determine its safety for man calls

² Autopsy 6th day after inoculation.

for a measure of comparison of the relative sensitivity of monkey and man to residual live virus in a vaccine. The inoculation of lots 6058 and 6039 into 32,000 children in the age group 6 to 8 years resulted in paralytic poliomyelitis in 17 of them (1). No extensive antibody surveys were made in Idaho prior to 1955, so the exact proportion of children susceptible to type 1 poliomyelitis is not known. However, in connection with the 1954 poliomyelitis vaccine evaluation study, scrums were obtained from children living in the more densely settled areas of Idaho and, of these, 50 percent had type 1 antibodies. These data indicate a paralytic attack rate of approximately 1 in 1,000 from 1 ml. of vaccine inoculated intramuscularly.

To attempt to get similar data regarding monkeys, the incidence of paralysis was recorded only on the basis of monkeys receiving a successful intraspinal inoculation. Although a total of 6.0 ml. of vaccine was given to each monkey, only the 0.5 ml. given intraspinally can be considered effective in producing paralysis. With lot 6039 the paralytic rates approach 50 percent for all virus types (table 8). With lot 6058 the rates are approximately one-third that of lot 6039 (table 9), but the results may have been influenced by the fact that lot 6058

was examined 6 to 8 months after studies of lot 6039 had been completed.

With both lots of vaccine, the incidence of paralysis was so much greater in monkeys than in children that a vaccine producing no paralysis in monkeys would be unlikely to have deleterious effect on children. If, along with absence of paralysis, no virus can be detected in blood, brown fat, or lymphoid tissue of monkeys, any chance of harmful effects on children appears remote.

Summary

The poliomyelitis vaccine, in two lots, which caused paralytic poliomyelitis in Idaho children in 1955 was studied in monkeys with the objective of detecting virus and comparing the relative susceptibility of children, as determined by observations in the field, and of monkeys, as determined by laboratory experiences.

A method of intraspinal inoculation which assured that the inoculum was actually placed in the spinal cord and inoculations of vaccine directly into lymphoid tissue and brown fat proved to be a most sensitive test for detecting virus in monkeys. Spinal cord, blood, lymphoid tissue, and brown fat all had to be examined for virus. The addition of merthiolate in a concentration of 1:10,000 to the vaccine aided in the isolation of type 1 poliovirus apparently by removing an interfering effect of type 2 virus.

With the methods of inoculation used, monkeys treated with large amounts of cortisone were at least 500 times more sensitive to the effects of the vaccine than children. Therefore, if virus cannot be detected in monkeys, ill effects in children appear very unlikely.

Table 9. Incidence of paralytic disease following inoculation of lot 6058, among animals with a successful intraspinal inoculation

Social Security Administration Seeks Eligibles

The Bureau of Old-Age and Survivors Insurance is making an intensive effort to find 400,000 people who may be eligible for payments under the 1958 amendments to the social security law and who must file their claims before benefits can start.

Among the more difficult to find are the estimated 60,000 parents who have survived their children and who were dependent upon them for support. Parents of deceased, insured workers are entitled to benefits even if a surviving spouse or child also gets payments.

Some others sought by the Social Security Administration's bureau are disabled workers 50-65 years of age who failed to qualify for benefits formerly because they did not meet work requirements in effect at that time; dependents of disability insurance beneficiaries; and disabled workers under 50 years of age who may have their earning records frozen to protect their rights to future benefits.

Under the law, a person is considered disabled if he is unable to do "any substantial gainful work," and his condition is expected to continue indefinitely. A person who applies for disability insurance benefits or to have his social security record frozen is requested to obtain a statement on his physical condition from his physician. The physician's clinical findings, along with the applicant's education, experience, and other pertinent factors, are studied by a team of trained people, including a physician, to determine whether the person is disabled and whether he can be rehabilitated. Members of State vocational rehabilitational agencies consider the possibility at that time of providing the disabled person with rehabilitative services.

Social security advisers in district offices will provide detailed information to those interested in filing applications.

Highlights of the

Social Security Amendments of 1958

THE SOCIAL SECURITY Amendments of 1958 (*1a*), signed by the President on August 28, 1958, will affect almost every American family both in benefits and in taxes. They will implement further the basic principles of the public assistance titles of the Social Security Act as expressed by Congress in the amendments enacted in 1956:

1. To help the aged attain self-care.
2. To help the blind and disabled attain self-support or self-care.
3. To help those responsible for dependent children to maintain and strengthen family life.

The amendments provide for increased benefits to old-age, survivors, and disability insurance recipients; higher social security taxes for workers and their employers and for the self-employed; an increase in the maximum earnings base for social security taxes and benefits; changes in eligibility requirements which will extend coverage to many individuals and families particularly in disability payments; increased flexibility of Federal participation in State-operated public assistance programs for the aged, blind and disabled, and for dependent children; increased appropriations authorized for each of the three programs under title V of

the Social Security Act (maternal and child health, crippled children's, and child welfare services); and extension of welfare services to children in urban areas on a par with children in rural areas.

Provision is also made for the establishment of advisory councils on child welfare services and on public assistance, similar to the existing Advisory Council on Social Security Financing.

The major amendments are summarized in the following paragraphs.

Old-Age, Survivors, and Disability Insurance

The amendments of 1958 provide for a revision of the financial basis of the old-age, survivors, and disability insurance program through increased benefits and contributions. In addition to strengthening the financial basis of the system, the amendments extend protection for the disabled through benefit coverage for dependents and through the elimination of certain restrictions, extension of the retroactive period for application for disability benefits, and modification of the work requirements for eligibility.

Higher Benefits

Effective with benefit checks for January 1959 (which will be mailed early in February) 12 million men, women, and children now receiving monthly old-age, survivors, and disability benefits will receive automatic increases of about 7 percent.

This report was prepared by Lucy M. Kramer, research analyst in the Division of Public Health Methods, Public Health Service, largely from materials of the Social Security Administration, and in consultation with members of its staff.

Retired workers aged 65 or over now receiving benefits ranging from \$30 to \$108.50 will receive \$33 to \$116. For a retired worker and spouse the maximum will be increased from \$162.80 to \$174.

Payments to dependents and survivors will be increased by about 7 percent also, with maximum payment to a family increased from \$200 to \$254. When several family members receive payments, each may not get the full 7 percent increase.

Disability insurance benefits to totally disabled workers aged 50-65, payable in amounts comparable to old-age insurance benefits, will also be increased by about 7 percent. Disability insurance benefits have been payable under the social security program since July 1957. About 225,000 persons with extended, total disabilities were receiving these benefits as of August 31, 1958.

The House Report on the Social Security Amendments of 1958 noted that wages had increased 12 percent and prices 8 percent since the last benefit increase was put into effect in 1954, and that old-age, survivors, and disability insurance benefits were a major source of income for most beneficiaries. "Clearly, since their benefits are such an important part of their income, the beneficiaries will be in real need if benefit amounts are not adjusted in the light of rising prices, wages, and levels of living" (2a).

Higher Taxes

Beginning in January 1959, the social security tax will increase from $2\frac{1}{4}$ to $2\frac{1}{2}$ percent for both employers and employees. The tax for self-employed persons will go up from $3\frac{3}{8}$ percent to $3\frac{1}{4}$ percent, beginning with 1959 earnings. Scheduled increases— $\frac{1}{4}$ of 1 percent for employers and workers and $\frac{3}{8}$ of 1 percent for the self-employed—will take place every 3 years instead of every 5 years as in the past, and will reach a maximum of $4\frac{1}{2}$ and $6\frac{3}{4}$ percent, respectively, in 1969 instead of 1975 (1b, 2b).

Effective January 1, 1959, the maximum annual earnings base for purposes of taxes and credit towards social security benefits will be increased from \$4,200 to \$4,800. As a result of the change, the maximum retirement benefit

will eventually be \$127 per month for a single worker and \$190.50 for a married worker and spouse 65 years of age or older.

The House Ways and Means Committee believed the rise in earnings levels made such an increase in tax base appropriate. "If the earnings base is not increased as wages rise, the wage-related character of the system will be weakened and eventually lost. In 1950 about 64 percent of regularly employed men would have had all their wages credited toward benefits under the \$3,600 base that was adopted in that year. The \$4,200 earnings base adopted in 1954 would have covered all the wages of about 56 percent of such workers. In 1957 only 43 percent had all their wages credited; about 56 percent would have received full credit under a \$4,800 base. An increase to \$4,800 would restore the situation which prevailed in 1954 and thus, in our opinion, would be a conservative adjustment to the rise in wages that has taken place" (2a).

Improvements in Disability Protection

For the first time, dependents of disabled workers who are receiving disability insurance benefits will receive social security payments. These payments are similar to those now provided for dependents of retired workers. Those eligible are wives and dependent husbands who have reached retirement age, unmarried dependent children (including sons or daughters disabled since childhood), and wives who have an entitled child in their care. As of September 1958 there were about 180,000 dependents of disability insurance beneficiaries who could become eligible for these monthly benefits.

The Social Security Amendments of 1958 eliminated the "disability benefits offset provision," of the law. Before the elimination of this provision, monthly social security disability payments (including childhood disability benefits) were reduced by the amount of any periodic benefit payable on account of disability under any other Federal program (except veteran's compensation) or a State workmen's compensation system. As of July 1958, about 40,000 disability insurance benefits (and about 1,000 childhood disability benefits) were either reduced or withheld as a result of this offset. Beginning in August 1958, the disabled can

receive the full amount of their social security benefits irrespective of any other payments based on disability. The House Ways and Means Committee stated (2c) that, since disability payments under the social security system are intended to provide basic protection against income loss from disabling illness, "it is undesirable, and incompatible with the purposes of the program, to reduce these benefits on account of disability benefits that are payable under other programs."

Another important amendment affecting the disabled changed the work requirements for both cash disability benefits and the disability freeze. The disability freeze preserves the disabled worker's future social security rights to benefits under the old-age and survivors insurance program. His wage record is frozen as of the date of disability. He is assured protection in the amount of benefits he receives at a later date.

Before the changes, to be eligible for either disability benefits or the disability freeze, the disabled worker must have worked in employment covered by social security for at least 5 years during the 10 years preceding disability, of which 1½ years must have been within the immediately preceding 3-year period. To be eligible for disability benefits, the worker must also have been fully insured, that is, he must have made social security contributions for half the 40 quarters in a 10-year working period prior to disability. The requirement of 1½ years out of 3 years, as applied to both the disability insurance benefits and the freeze, was eliminated, and fully insured status was added as a requirement for eligibility for the freeze. Thus, as a result of the amendments, to qualify for disability benefits or the freeze, the worker must be fully insured and must have about 5 years of covered work during the 10-year period that ends with the onset of his disability. As a result of the changed work requirements, about 35,000 persons who could not qualify for disability insurance benefits under the previous requirements can, upon filing application, become immediately eligible for benefits. In addition, about 15,000 persons can qualify immediately for a disability freeze.

The deadline for filing fully retroactive applications for the disability freeze—that is, ap-

plications which permit a disability freeze to be established as early as the actual onset of disability—was extended for 3 years, from June 30, 1958, to June 30, 1961. Under prior law, a disability freeze based on an application filed after June 30, 1958, could begin no earlier than 1 year before application. The postponement of the deadline for filing fully retroactive freeze applications made it possible (if applications are filed) for about 30,000 additional disabled workers to become immediately eligible for disability insurance benefits and an additional 10,000 to become immediately eligible for the freeze.

The amendments also provide for retroactive payment of disability insurance benefits for as many as 12 months before the month in which application is filed for these benefits. Applications for disability insurance benefits are thus accorded the same retroactive status as applications for all other types of monthly benefits under the program.

Public Assistance

The Federal matching formula for public assistance has been changed in three major respects, which, in addition to affecting payments for income and maintenance, have an impact on medical services for public assistance beneficiaries and are of particular significance to public health.

Average Maximum

Effective October 1, 1958, the matchable maximum for Federal contribution to the States, for their aged, blind, and disabled programs, has been set at \$65 per month per recipient, with the matchable maximum determined by averaging the combined money and vendor payments in each State for the total number of recipients. For aid to dependent children, the maximum has been set at \$30, with the matchable maximum also determined by an average based on the total number of recipients. The provision for a lower maximum of Federal participation (\$23) for additional dependent children after the first in the same family has been eliminated, so that the average maximum is applicable to all children and to the needy adult caring for them.

The effect of this amendment will be to increase the Federal share of assistance payments. With only 1 or 2 exceptions, States had not been receiving the maximum money payments available under the prior limit of \$60 for Federal participation. Under the new provisions, the maximum total amount in which the Federal Government participates will be increased, and, for States with low per capita income, the percent of Federal participation will also be increased. In the event that families or persons are responsible for more than one dependent child, States will be provided with additional Federal funds that may be used to increase assistance payments. In addition, administrative and fiscal procedures will be simplified under this amendment.

For payments to the aged, blind and disabled, the Federal share will still be $\frac{1}{3}$ of the first \$30 per recipient, but for the remainder, up to a new average maximum of \$65, the Federal participation will vary with State and national per capita income. For aid to dependent children programs, the Federal share remains $\frac{1}{17}$ of the first \$17 per recipient, but for the remainder, up to a new average maximum of \$30, it will also vary with per capita income.

Variable Grants

Effective October 1, 1958, the previous 50-50 matching of Federal funds above the first part of the average amount per recipient, but within the overall limits, has been changed to a variable range of 50 to 65 percent, based on the average per capita income of a State during the 3 most recent calendar years. This would limit Federal participation to 50 percent for those States whose per capita income is equal to or above the national average for the same period, and allow an upward range to 65 percent for those States whose per capita income is below the national average.

The present law requires the Secretary of the Department of Health, Education, and Welfare to promulgate in alternate even numbered years the Federal percentage of participation for each State.

The Federal percentage of financial participation in State public assistance expenditures, following the initial promulgation (3), is

shown in table 1 for the period October 1, 1958, to June 30, 1961.

For the new Federal matching procedure, a research note prepared by the Division of Program Research of the Social Security Administration summarizes estimates of total and per capita personal income for 1957 alone and for 1955-57 (4). It tabulates by States the ratio of State to national per capita income in order of magnitude for 1957, and compares the results with the 3-year average.

Per capita personal income in 1957 averaged \$2,027 for the continental United States, 3 percent above the average for 1956 of \$1,961. By State, the 1957 average per capita income varied from \$958 in Mississippi to \$2,821 in Connecticut. The range of \$1,863 between the lowest and highest income State went from more than 50 percent below the national average to 39 percent above. When the Federal formula grant is applied in terms of 3-year averages, the order of rank changes with lessening of annual fluctuation. Mississippi remains lowest of the bottom 12 States with an average of \$968. Connecticut no longer ranks first but is second in the top 12, with an average of \$2,678. Delaware is first with \$2,744. Twenty States retain their rank; the rest shift.

The House Ways and Means Committee expressed the belief (2d) that the revised formula "will be of particular assistance to States with limited fiscal resources and will enable these States to make more nearly adequate assistance payments. This will help to more nearly balance the level of assistance made available to needy people in various parts of the country."

Combined Money and Vendor Payments

Effective October 1, 1958, the Federal maximum share of public assistance includes and permits payments by the State to public assistance recipients for all types of aid including medical care. It eliminates the separate matching of payments to vendors, such as doctors, dentists, nurses, and hospitals, in the fixed Federal maximums of \$6 per adult recipient and \$3 per child.

Heretofore, under the 1956 Amendments to the Social Security Act which operated for a little more than a year (from July 1, 1957, to October 1, 1958), assistance payments for medi-

cal care were made by States either directly to recipients or to recipients and vendors combined or to vendors directly on behalf of a needy person, within fixed limits to which the Federal funds could be applied.

The types of medical care covered included practitioners' services, hospitalization, drugs, nursing-convalescent home care, dental services, nursing services, clinic services, prosthetic appliances, ambulance or other transportation, laboratory, and X-ray services.

A comparison of January 1957 with January 1958 shows that in each of the four programs using public assistance medical care (old-age

assistance, aid to dependent children, aid to the blind, and aid to the permanently and totally disabled), the number of States using the vendor method of payment for medical services increased in all but one of the types of medical care: nursing homes for the aged and for the disabled (5). For the same period, the total amount of all vendor payments increased also, but the number of cases for which only vendor payment was made decreased.

Table 2 compares the amount of vendor payments for medical care and the number of cases in which vendor payments only were made for January 1957 (under the old system of com-

bined money-vendor payments within the specified maximum) and for January 1958 (under the provisions in effect from July 1, 1957, to October 1, 1958, which permitted a choice of the old system or the separate Federal matching vendor program).

Federal participation in direct payments to vendors was first made possible under the 1950 Social Security Amendments (6,7). The amount, however, for medical care in which the Federal Government could participate had to remain within the specified individual matchable assistance payment maximums.

Table 3 gives the total State and Federal vendor payment for medical care from 1951 through 1957, and a breakdown into the categories of use: old-age assistance, aid to dependent children, to the blind, and to the permanently and totally disabled, and general assistance. The increase in vendor medical payments is the result of several factors, among which are the increase in the cost of medical care and the increase in the number of States providing medical care and thus participating in Federal funds.

A pooled fund (in effect a prepayment monthly arrangement per recipient) was used by public assistance agencies within some States to permit greater flexibility in individual medical care cases. The averaging of costs made possible through the pooled fund arrangement helped to some extent to meet increasing medical needs and costs. The funds available for medical care for needy persons were limited, and

only a few States took advantage of Federal contributions to offset such costs.

In fiscal year 1957, only about 10 percent (\$288 million) of the total \$3 billion expended for public assistance went to vendors directly. About 20 percent of the \$288 million, or 2 percent of the total came from Federal funds. Most vendor payments were made by a few States with the greatest resources. For example, more than half of the vendor payments for aged persons in June 1956 were made in three States: New York, Illinois, and Massachusetts. A few States made vendor payments entirely from State and local funds (8).

To increase funds for medical care for the needy, the Social Security Act was amended again in 1956 (9), effective July 1, 1957, fixing Federal matching maximums for medical care at $\frac{1}{2}$ the product of \$6 times the number of adult recipients and $\frac{1}{2}$ the product of \$3 times the number of child recipients per month. This provision for fixed Federal matching for medical vendor payments was supported by many professional and medical organizations.

Before the 1956 Amendments were put into effect, and because the new fixed maximum vendor payments would penalize some States, new legislation was passed in July 1957 (10). Under the legislation, it was optional with a State whether it use the combined money-vendor payments within the specified maximum or whether it claim separate Federal matching for vendor-medical care payments. Only two States, Illi-

bined money-vendor payments within the specified maximum) and for January 1958 (under the provisions in effect from July 1, 1957, to October 1, 1958, which permitted a choice of the old system or the separate Federal matching vendor program).

Federal participation in direct payments to vendors was first made possible under the 1950 Social Security Amendments (6,7). The amount, however, for medical care in which the Federal Government could participate had to remain within the specified individual matchable assistance payment maximums.

Table 3 gives the total State and Federal vendor payment for medical care from 1951 through 1957, and a breakdown into the categories of use: old-age assistance, aid to dependent children, to the blind, and to the permanently and totally disabled, and general assistance. The increase in vendor medical payments is the result of several factors, among which are the increase in the cost of medical care and the increase in the number of States providing medical care and thus participating in Federal funds.

A pooled fund (in effect a prepayment monthly arrangement per recipient) was used by public assistance agencies within some States to permit greater flexibility in individual medical care cases. The averaging of costs made possible through the pooled fund arrangement helped to some extent to meet increasing medical needs and costs. The funds available for medical care for needy persons were limited, and

only a few States took advantage of Federal contributions to offset such costs.

In fiscal year 1957, only about 10 percent (\$288 million) of the total \$3 billion expended for public assistance went to vendors directly. About 20 percent of the \$288 million, or 2 percent of the total came from Federal funds. Most vendor payments were made by a few States with the greatest resources. For example, more than half of the vendor payments for aged persons in June 1956 were made in three States: New York, Illinois, and Massachusetts. A few States made vendor payments entirely from State and local funds (8).

To increase funds for medical care for the needy, the Social Security Act was amended again in 1956 (9), effective July 1, 1957, fixing Federal matching maximums for medical care at $\frac{1}{2}$ the product of \$6 times the number of adult recipients and $\frac{1}{2}$ the product of \$3 times the number of child recipients per month. This provision for fixed Federal matching for medical vendor payments was supported by many professional and medical organizations.

Before the 1956 Amendments were put into effect, and because the new fixed maximum vendor payments would penalize some States, new legislation was passed in July 1957 (10). Under the legislation, it was optional with a State whether it use the combined money-vendor payments within the specified maximum or whether it claim separate Federal matching for vendor-medical care payments. Only two States, Illi-

believes that the present law should be amended so as to make child welfare services generally available not only in rural areas but also in urban areas and to give equal consideration to children in urban areas as to children in rural areas."

This change does away with inequities in the prior law, since 3 out of 5 children in the Nation now live in urban areas, and the rural-to-urban shift in population continues.

The allotment formula has been modified accordingly, so that allotments of child welfare funds will be in direct proportion to the total population under 21 years of age and in inverse proportion to State per capita income, with the protective proviso that no State shall receive less than it would have prior to the amendments of 1958 under an appropriation of \$12,000,000. Previously, allotment was primarily on the basis of rural child population under the age of 18. Furthermore, the new statute requires that Federal child welfare funds be matched with State and local funds beginning with fiscal 1960. Heretofore States were required to pay "part of the cost" for services in predominantly rural areas.

The Children's Bureau, beginning with the nationwide conference of State public welfare administrators, held early in October 1958, is giving special help to the State agencies in regard to the amendments, particularly as they affect the extension of services to urban areas (11). The Federal share and the allotment percentage for each State under the new formula has been published in the Federal Register (12). The Handbook for Child Welfare Services has already been revised to reflect the changes in Federal policy produced by the amendments which are now in effect.

An Advisory Council on Child Welfare Services has also been established, under the amendments, to make recommendations to the Secretary of Health, Education, and Welfare on the effective extension of child welfare services beyond rural areas. It is also to be composed of 12 members, appointed by the Secretary, and representing voluntary, civic, religious, and professional welfare organizations and the public (14). It is to report its findings and recommendations not later than January 1, 1960.

Hospitalization for OASI Beneficiaries

The House Ways and Means Committee, in its report on the Social Security Amendments of 1958, took cognizance of the needs of the aged for hospital and nursing services. It referred to the various bills introduced into the 85th Congress that would broaden the old-age, survivors, and disability insurance program to provide payment for such services to OASI beneficiaries. In its public hearings on social security (2g), the committee heard testimony to the effect that "under existing arrangements, insurance against the costs of needed hospital and nursing home services is out of reach of many older people," and concluded that "there appears to be a need for making this protection available to older people."

However, the committee believed that before legislation could be considered or recommendations entertained, a study of the practicability and costs and of alternative methods of providing such protective insurance to OASI beneficiaries was needed. The alternatives, the committee held, should include a possible prepayment plan whereby a worker, during his years of employment, could make additional social security contributions which would be used to buy hospital and nursing care insurance from private and nonprofit health insurance organizations. For each of the alternatives considered in the study, there should be an evaluation of the cost of the benefits and the administrative implications.

The committee asked the Secretary of Health, Education, and Welfare to conduct such a study and report back to Congress by February 1, 1959.

Summary

The Social Security Amendments of 1958 provide for a revision of the financial structure of the OASI program through increased benefits and an increase in the maximum earnings tax base. They also provide for improvements in the protection of disabled OASI recipients.

In public assistance, new principles of average maximum matchable payments and variable grants based on per capita income have been introduced. Separate matching for ven-

nois and New Hampshire, chose to continue using the old system of combined payments within the specified maximum, for selected adult programs. Illinois continued it for the aged, blind, and disabled payments, and New Hampshire for the aged and disabled.

However, separate Federal matching for vendor medical payments did not allow the States sufficient flexibility in providing medical care for the needy, and was eliminated with the 1958 legislation. In place of a money payment maximum of \$60 and a maximum of \$6 per vendor medical care payments for adults, and \$32 and \$3 respectively for children, there is an average maximum for all public assistance (including medical care payments) of \$65 for adults and \$30 for children in which the Federal Government participates.

Table 4 compares the method of computation of Federal sharing under the old formula in effect until October 1, 1958 (separate money and vendor medical payments), and under the 1958 amendment (combined money and vendor medical payments), effective October 1, 1958.

The 1958 amendment gives the State greater flexibility in allocating funds for medical care between recipients and vendors without loss in Federal funds. The decision on method of payment for medical care can rest on the State's determination of what is best for the recipient and for its own administration.

Under the new amendment, medical care payments are still available to public assistance recipients, with Federal participation, but the amount and method of payment are determined by the needs of the State rather than by the policy of the Federal Government. A person whose income is sufficient to meet all but medical needs can be counted as a recipient for the total public assistance average in which the Federal Government will participate, if he is also established as a case of need, under the standards of assistance of each State. That is, States may now get the higher Federal matching provided for the first fraction ($\frac{1}{2}$ of \$30 for adults and $\frac{1}{17}$ of \$17 for children) in cases receiving vendor medical payments only, provided that a State has validly established that these persons are eligible for public assistance.

According to the House Report (2e), "This change will enable a State to decide to what

extent it wishes to pay for medical care received by the needy through the method of making a payment in his behalf to the vendor of the medical care or giving him money so that he can purchase his own medical care, without being influenced by consideration of Federal financial sharing."

An Advisory Council on Public Assistance, appointed by the Secretary of Health, Education, and Welfare, has been established to review the existing public assistance programs in relation to old-age, survivors, and disability insurance, the fiscal capacities of the States and the Federal Government, and any other factors relating to the amount and proportion of State and Federal sharing in the public assistance program (1c). It is to be composed of the Commissioner of Social Security and 12 other persons, including employer and employee representatives and experts in State and Federal administrative and fiscal programs. It is to report back to the Secretary not later than January 1, 1960.

Maternal and Child Welfare

Maternal and child health services, crippled children's services, and child welfare services (the three grant programs covered by title V of the law) have all received substantial increases in annual authorized appropriations, and to that extent the changes are significant for the national health outlook. The increases in annual amounts authorized are as follows: maternal and child health services, from \$16,500,000 to \$21,500,000 (30.3 percent); crippled children's services, from \$15,000,000 to \$20,000,000 (33.3 percent); and child welfare services, from \$12,000,000 to \$17,000,000 (41.7 percent).

Certain child welfare provisions in the old law have been eliminated. Provisions specifying the use of Federal child welfare funds in predominantly rural areas or other areas of special need have been set aside; services are now extended to urban and rural children on the same basis.

According to the House Report (2f), "Many families have shifted in the last decade from farms and small towns to cities where services have not expanded to meet their needs. In the light of these developments, your committee

A Migrant Labor Crisis in Immokalee

WILSON T. SOWDER, M.D., M.P.H., and JOSEPH LAWRENCE, M.D.

SHORTLY BEFORE Christmas in 1957, temperatures in many parts of Florida fell below the freeze level, the lowest they had been in 40 years. The freeze damaged the citrus crop and wiped out vegetable plantings. When growers planted new vegetable crops, these were flooded and rotted by unseasonable rains. The weather not only cost the growers a fortune but brought destitution to thousands of migrant laborers who came to work the crops.

Their plight was especially pressing in the area of Immokalee, an unincorporated town with about 3,000 permanent residents. Immokalee lies removed from the opulent Florida "Gold Coast," below Lake Okeechobee, in Collier County, which is twice the size of Rhode Island, with a total population of about 14,000.

Spoken of as "the last frontier" in Florida, Immokalee is little more than a row of buildings briefly flanking a broad highway, hemmed in by large landholdings and the waters of the Everglades. Ponds or puddles covered much of the town. Of its 1,200 houses, only 5 percent are in good condition. About 85 percent are best described as shacks. In season, this town typically is called on to accommodate 8,000 migrant farm laborers and their families.

Most of the so-called labor camps in the district are in deplorable condition. Shallow wells provide the water supply. There are a few septic tanks and many privies, but many

dwellings lack toilets of any kind. There are no garbage collections.

A single health department serves both Collier and adjoining Lee County (population 38,000). The health department operates a fairly well-equipped clinic in Immokalee in a building about 25 by 50 feet. (A new modern health center is being constructed under the Hill-Burton program.) Normally this clinic receives about 25 patients daily and sees about 20 expectant mothers weekly.

The usual staff of the health department, numbering 11 in Collier County, was augmented by special funds obtained from the Children's Bureau and the State for health work with migrants. In addition, one nurse, a physician, and a sanitarian were recruited for the period of crisis. The staff included an interpreter to speak with the migrants of Spanish culture, from Puerto Rico, Mexico, or Texas, at least a fourth of the total.

Late in December the editor of the town weekly was asked by several hungry migrants for something to eat. He found more than 60 families in desperate need of warm clothing and food. On December 27 he telegraphed the Governor of the State to ask for assistance. Pursuant to this appeal, on January 2, the Red Cross declared Immokalee a disaster area.

In the absence of a welfare office, the health department was asked to certify needy residents to be eligible for supplies of Federal surplus food. The clinic was swamped with applicants, and clerks were recruited from the office of the county commissioners to free the health department staff for normal duties.

Meanwhile, Miami and Tampa newspapers and national broadcasts stimulated donations of tons of food and clothing and several thou-

Dr. Sowder is State health officer of the Florida State Board of Health and Dr. Lawrence, health officer of Lee and Collier Counties. This article is based on a paper presented by Dr. Sowder and Dr. Lawrence before the Southern Branch, American Public Health Association meeting on May 8, 1958, at Little Rock, Ark.

dor medical payments has been eliminated. An advisory council has been established to review existing public assistance programs, and the fiscal capacities of State and Federal Governments with respect to the public assistance program.

For the three programs under title V of the Social Security Act (maternal and child health, crippled children's, and child welfare services), increased annual appropriations have been authorized.

In child welfare, financial allotments on the basis of the rural child population have been eliminated, and services will now be extended to urban and rural children on the same basis. Beginning with fiscal 1960, Federal child welfare funds will be matched with State and local funds. An advisory council has been established to make recommendations on the effective extension of child welfare services beyond the rural areas.

The House Ways and Means Committee requested the Department of Health, Education, and Welfare to study the hospital and home nursing needs of the aged OASI beneficiaries. The study is to include practicability and costs of protective insurance and alternative methods of providing it. The study is to be completed by February 1, 1959, and made available to Congress.

plies and a long-term program of housing and sanitation. In the interest of health, they recommended an emergency sanitation and clean-up campaign, using the labor available in the community. The Governor and Cabinet, sitting as a budget commission, granted \$15,000 to purchase food and \$30,000 for the emergency work, promptly labeled by the press as a "Baby WPA."

Within a few hours, the county health officer was advised that he had responsibility for directing the emergency project. The funds became available on February 4, and the project was scheduled to start on February 11. On that day, work began with 37 hands.

In the meanwhile, a squad of State employees, including an entire class of sanitation trainees, had been sent to Immokalee to assist in developing the operation. Meeting on February 6 with local officials, the director decided to recruit one person from a family, with priority to heads of the largest families, and pay him \$5 a day, \$1 below the prevailing wage offered by local growers. It was planned to spend \$2,000 a week for 12 weeks, allowing each family at most 1 or 2 days employment per week.

Workers were identified by metal tags, and wages were paid on the spot at the end of each day, in silver dollars. (Most of these dollars were used to pay for groceries or gasoline, or to

To erase the health hazard from the tremendous amount of refuse in Immokalee's vacant lots and yards, the project opened with a sanitation and clean-up campaign using migrant labor teams.

support the churches.) To be eligible for re-employment, workers were also required to report for typhoid immunization shots.

As the Governor had directed other State agencies to assist the project, there was an ample supply of trucks with drivers, shovels, picks, lazy boys, rakes, hoes, and other equipment, including an airplane to carry the State health officer to Immokalee on missions of inspection.

The sanitation work was mapped out by a sanitary engineer and aides. He indicated the areas to be drained, direction of ditches, and areas to be filled. Sanitation trainees surveyed the town to appraise housing, water sources, and sewage disposal. By the end of February, plans were well enough established that most of the State health department employees were removed.

One of the first tasks of the work crews was to haul garbage, rubbish, and trash from yards and streets. They collected about 25 truckloads every day for 2 months. Others completed about 20,000 feet of drainage ditches, so that the town is now dry for the first time in its history. Spraying and rat-trapping, directed by an entomologist from the State office, reduced the vector population.

A few people continued to work on a plan to convert the grounds of a school used by Negro children into a recreational area and laundry facility. The ground level was raised by several dozen loads of dirt, the basketball court

Migrant laborers dug ditches and drained impounded water in the Immokalee area, cutting down the vector population considerably. Whether the town remains dry depends not only on the weather but on the townspeople keeping ditches free of trash.

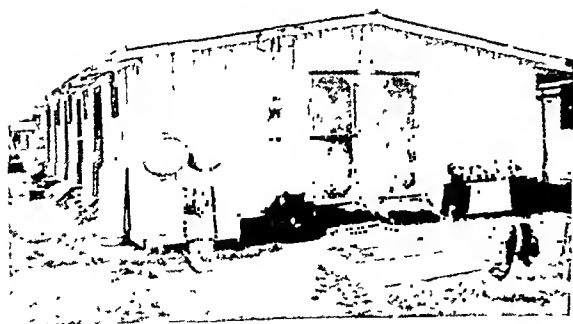

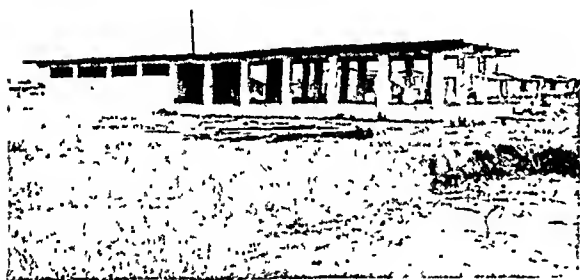

sands in cash. Ample supplies of antibiotics, vitamins, and baby foods were contributed by manufacturers. Soup kitchens were set up by local churches and the Salvation Army, and on January 9 the first regular deliveries of food were received by needy families. These continued through April.

The donations were given over to the management of a long-standing local committee on migrants, under chairmanship of a local minister. The committee set up a register of needy persons, both local and migrant. More than half of the migrants by this time had left the area.

The first rise in demand for medical services began in January. The illness consisted mainly of diarrhea among children and obvious effects of malnourishment of infants and chil-

Women migrant workers played a stellar role in the health project. They are shown here whitewashing a house, one activity of many which left the town tidier and more livable than ever before.

A tangible product of Immokalee's emergency project is the new community building in construction (top). Beneath is a migrant shack which housed eight families. Entrances to individual apartments are on the left.

dren. On January 16 a Public Health Service physician, on assignment to the central office of the Florida State Board of Health, was sent to Immokalee so that a doctor would be on call around the clock. The clinic was then receiving about 100 patients daily.

Reports of two cases of paratyphoid fever sparked an immunization campaign. To explain the need for inoculations leaflets in the Spanish language were circulated through food distribution centers. A sound truck traveled through the community urging all to come to the health department for protection. In 6 weeks the clinic performed about 3,000 complete typhoid immunizations. The least response came from the permanent residents of the town.

On January 30, at the request of the Governor, the adjutant general of the Florida National Guard and the State health officer personally investigated Immokalee, in company with the director of the Florida State Department of Public Welfare. They found no one in need of medical services who had not obtained them. Free hospitalization had been provided under the State-County indigent hospitalization program, available even to nonresident patients. Food supplies were found to be adequate, but not completely satisfactory, as many families missed their customary diet.

The investigators recommended to the Governor the purchase of supplementary food sup-

¹ Includes foreign nationals. Leaders (-----) indicate no specialization offered at this level.

During the period of July 1956 through June 1957, graduate degrees in sanitary engineering were conferred on 163 individuals by institutions in the United States: 152 master's

degrees and 11 doctor's degrees. In the same period, 145 students completed undergraduate programs specializing in sanitary engineering.

Prepared by Frederick K. Erickson, S.M., and Frank A. Butrico, M.S.S.E., Office of Engineering Resources, Division of Sanitary Engineering Services, Public Health Service. Mr. Erickson is sanitary engineer director, and Mr. Butrico, chief of the office.

The tabulation above shows the institutions in the United States awarding sanitary engineering degrees and the number and level of the degrees conferred, irrespective of the nomenclature of the degree. The totals are those reported by the institutions. A list of all schools offering such training is available from the authors. Similar data for the period since

was repaired and given a blacktop surface, and a baseball diamond was laid out. A new community building, 20 by 80 feet, of cement block, will house toilets, showers, laundry tubs, and a recreation hall.

Many wild dogs that haunted the town were caught and impounded as a phase of the program. Those unclaimed for 3 days were sent to the Miami Humane Shelter.

Women, who headed many needy families, were engaged in special projects of whitewashing houses, cleaning yards, home care for the disabled, gardening, staffing food distribution centers, attending children, and other light work. They also distributed handbills for the immunization campaign.

Perhaps the most important gain fostered among these women was their response to the health information offered by the public health nurses and others in the department. This gain promises to be at least as permanent as the

new gardens, the whitewashed walls, and the disposal of trash and garbage.

Another significant effect of the crisis is that the local physician, who was on the point of seeking another situation, has agreed to work for the county on a part-time basis and to remain in practice in Immokalee. The State hopes to develop a plan whereby hospitals and medical schools will assign general practice residents to this area for a few months at a time.

The manner in which this small county health unit handled a community crisis with disastrous possibilities was materially influenced by the public response to the facts reported by the local editor, by the availability of Federal surplus foods, by the law providing hospitalization of the indigent, the State mosquito control program, Federal and State support for health services for migrants, and other resources of the State.

National Conference on Homemaker Services

A national conference on homemaker services, designed to stimulate development of these services throughout the Nation, will be held February 10-11, 1959, in Chicago. This multidiscipline conference is sponsored by 26 national voluntary agencies and by the Office of the Commissioner, the Bureau of Old-Age and Survivors Insurance, the Bureau of Public Assistance, and the Children's Bureau, of the Social Security Administration; the Public Health Service; the Office of Vocational Rehabilitation; the Office of Education; and the Special Staff on Aging of the Office of the Secretary of Health, Education, and Welfare.

Twelve preconference study groups have scheduled meetings in various cities to prepare policy statements on the development and operation of homemaker services. Other preconference materials include a pamphlet explaining homemaker services; descriptions of different types of such programs; and a nationwide survey of agencies supplying the services.

Conference chairman is Mrs. R. Livingston Ireland, director of the Ohio Department of Public Welfare and executive secretary is Mrs. Lucille M. Smith, chief of Health Services Organization Branch, Division of Public Health Methods, Public Health Service.

ter's degrees per year for the 10 years 1948-57. The average number of master's degrees conferred per year for the 10-year period 1947-56 was 133, and for the 5-year period 1952-56, 117.

Doctor's Degrees

Six institutions in 1957 awarded a total of 11 doctor's degrees, conferring 10 on United States citizens. Twenty-six other institutions offering sanitary engineering training at the doctorate level reported no doctor's degrees awarded.

Three of these 6 schools have awarded one or more doctor's degrees each year for the past 5 years and during that period have accounted for over 60 percent of the doctorates in sanitary engineering. For the 10-year period 1947-56,

the average number of doctor's degrees per year was 6.3, and the average for the 5 years 1952-56 was 8.6 degrees.

Division of Public Health Nursing

A Division of Public Health Nursing has been established in the Bureau of State Services.

The new division, as a focal point for public health nursing in the Public Health Service and through its consultative services, provides leadership in extending and improving public health nursing services in order to implement public health programs and to plan for the nursing care of ill and disabled persons who are at home.

Through its working relationships with State and national groups it represents the Public Health Service in the development of public health nursing standards of preparation and practice.

The Division of Public Health Nursing staff arranges for assigning public health nurses to educational institutions and field agencies for career development purposes and gives professional guidance to public health nurses assigned to the various programs within the Public Health Service. It conducts research in relation to public health nursing practice and advises on studies conducted by State and local agencies.

Officials of the Division of Public Health Nursing are Margaret G. Arnstein, chief; Zella Bryant, deputy chief; Frances E. Taylor, chief of Training and Career Development Branch; Doris E. Roberts, chief of the Operational Research Branch; Dr. Marion Ferguson, consultant in studies; and Mary Vesta Marston, consultant in operational research.

Undergraduate Degrees

Forty-three institutions offered a program in sanitary engineering during the academic year 1956-57. Of these schools, 31 reported 145 graduates had received undergraduate training toward the bachelor's degree in sanitary engineering or had a sanitary engineering major or option. The average number of graduates per

year for the 10-year period 1947-56 was 200 and for the 5-year period 1952-56, 189.

Master's Degrees

Of the 64 colleges and universities offering graduate training in sanitary engineering, 23 schools, or 36 percent, reported no graduates. The remaining 41 schools awarded 113 degrees to United States citizens and 39 degrees to foreign nationals.

The bulk of training in 1957 was done by 16 schools. These schools trained 111 students and had 4 or more graduates per school. Of these 16 schools, 7 have averaged over 5 mas-

not until 1930 that Meyer and his co-workers isolated the etiological agent (3). The largest outbreaks of equine encephalitis ever recorded occurred in 1937 and 1938 when over one-third of a million equine cases with a mortality of 20 percent were reported from the 22 States west of the Mississippi River. Iowa holds the all-time record of 66,000 cases in 1 year (1938). During a recent 5-year period (1952-56), reported cases of equine encephalitis for the 22 western States averaged 1,350 cases per year, according to U. S. Department of Agriculture reports.

When Howitt recovered the WE virus from a child's brain in 1938, it was proved that the term "western equine encephalomyelitis" was a misnomer (3). Three years later the greatest human epidemic of WE occurred. At least 3,000 persons were attacked, including 1,100 in North Dakota. No large epidemic of WE has occurred since 1952, when California reported more than 700 human cases, of which 375 were confirmed as WE (4).

The fatality rate for WE averages from 20 to 30 percent in horses and 5 to 15 percent in humans. Severe and permanent aftereffects can follow the disease, especially in infants. Many cases of this disease occur in infants and to a lesser extent in persons over 50 years old; clinical infections are usually uncommon at the other ages. However, in the 1941 epidemic in North Dakota, about 37 percent of the cases occurred in the age group 15-44 years (5).

Proof that the WE virus could be transmitted by mosquitoes (*Aedes aegypti*) was obtained by Kelser's classic experiments in 1933 (6). It was not until 1941, however, that Hammon and his associates reported the first WE virus isolation from a mosquito in nature, *Culex tarsalis* (7). Since 1941, *C. tarsalis* has been considered the primary vector of WE. To date, the WE virus has been isolated from several hundred pools of this species, collected in 11 States and the Province of Manitoba, Canada. The geographic distribution of *C. tarsalis* corresponds to the general distribution of the WE virus. This vector is common west of the 95th meridian, roughly the 17 western States, and in the entire State of Iowa, where it breeds in great numbers in seeps and grassland surface pools. *C. tarsalis* fits the role of a primary vector very well

because of its abundance in western areas; its tendency to feed readily on a wide range of hosts, including birds, cows, horses, and man (8); and its remarkable laboratory vector efficiency in transmitting the WE virus (9).

Studies made since 1941 show that wild birds are commonly infected with the WE virus. Virus recoveries have been made from approximately 20 species in nature. Domestic fowl also may serve as natural hosts from which mosquitoes become infected.

Factors favoring outbreaks of WE include an abundance of *C. tarsalis*, particularly early in the season. With respect to the epochal outbreak of encephalitis in North Dakota in 1941, it may be significant to note that the year 1941 was the wettest year in the climatologic history of North Dakota, according to a personal communication from F. J. Bavendick, U. S. Weather Bureau, Bismarck, N. Dak. The California epidemic of 1952 was preceded by one of the heaviest snow packs ever recorded on the mountain ranges of this State; the subsequent melting of the snow, coupled with moderate winter and springtime temperatures, resulted in a flood which caused an early season buildup of vector populations (10).

Eastern Encephalitis

Eastern encephalitis was first recognized as a distinct disease entity in 1933 (11, 12). It has since caused intermittent outbreaks among horses, humans, and birds in various sections of eastern United States, principally in coastal States from Massachusetts to Texas.

Eastern encephalitis was first recognized as a disease of man in 1938 in Massachusetts (13, 14). Since 1938, there have been reported less than 100 human cases for the entire Nation, but 50 of these cases have occurred in Massachusetts—34 in 1938, 4 in 1955, and 12 in 1956 (15)—and 18 in Louisiana. In 1957, Florida reported two confirmed human cases of EE for the first time (personal communication from J. O. Bond, Florida State Board of Health, Jacksonville).

Most of the outbreaks among horses have comprised not more than a few hundred cases. One exception was the epizootic in 1947 in Louisiana, when 14,334 cases and 11,722 deaths were reported.

Status of Mosquito-Borne Encephalitis in the United States

LESLIE D. BEADLE, M.A.

MOSQUITO-BORNE encephalitis infections are relatively new diseases from the standpoint of definite knowledge; however, such diseases probably have existed in this country and in other parts of the world for centuries. In the United States the three principal encephalitis viruses—western, eastern and St. Louis—were first isolated in the early 1930's, but there is good evidence that outbreaks of sleeping sickness among horses occurred over 100 years ago. Recently, Hanson described an epizootic of encephalitis, probably the eastern type, among 100 horses in southeastern Massachusetts in 1831 (1).

The present status of the human encephalitis problem is difficult to evaluate because routine reporting of "infectious encephalitis" by physicians is based on clinical symptoms rather than on cause. Encephalitis means inflammation of the brain, but such inflammation can be caused by a host of agents, living and nonliving, including chemicals, protozoa, bacteria, rickettsiae, fungi, and viruses. Our most accurate information on distribution of the mosquito-borne encephalitis viruses and the magnitude of the problem they create is obtained by special studies when epidemics and epizootics occur. During the past 25 years, severe outbreaks in horses and man have occurred periodically in various parts of the United States.

Present knowledge concerning the natural history of these virus diseases indicates that

wild birds are the principal reservoirs of infection and mosquitoes are the vectors. Normally the infection chain is limited to birds and mosquitoes. Under certain conditions, the virus spills over to horses, humans, and other mammals. Man and equines appear to be dead-end hosts and are not important in the natural cycle. There is no evidence that either is a significant source for mosquito infection.

The encephalitis viruses cause infections in a wide range of vertebrate hosts, but in many hosts, such as birds, the infections are apt to be mild or entirely asymptomatic; among humans and horses, they range from the clinically inapparent type to a severe, highly fatal involvement of the central nervous system.

Common symptoms of mild cases in man include a brief fever, malaise, or a headache. Among the more prominent signs and symptoms of severe infections are an abrupt onset, high fever, severe headache, stiff neck, irritability, drowsiness and coma, muscular twitching, and convulsions. The symptoms sometimes are confused with those of poliomyelitis, but residual paralysis is not common.

In this paper the current status of knowledge concerning western encephalitis (WE), eastern encephalitis (EE), and St. Louis encephalitis (SLE) will be briefly reviewed.

Western Encephalitis

The western encephalitis virus has been most active in States west of the Mississippi River and in Wisconsin and Illinois. The "cerebrospinal meningitis" in Idaho in 1897 and the famous Kansas-Nebraska horse plague of 1912 undoubtedly were caused by WE; but it was

Mr. Beadle is chief biologist, Water Resources Activities, Communicable Disease Center, Public Health Service, Atlanta, Ga. This paper was presented at the 29th annual meeting of the Florida Anti-Mosquito Association, Clearwater, Fla., April 28, 1958.

the United States. This type of encephalitis derives its name from the serious epidemic which was centered in St. Louis and St. Louis County, Mo., during the late summer of 1933. More than 1,100 human cases were reported in the city and county.

Distribution of the SLE virus is not so clearly delineated as that of the WE and EE types since the horse does not serve as a sentinel animal for SLE infections. In general, the virus occurs throughout the western and central States. An unusual record was obtained last summer, when the virus was recovered from the spinal fluid of a patient in Plant City, Fla. (personal communication from J. O. Bond, Florida State Board of Health, Jacksonville).

St. Louis encephalitis outbreaks appear to be of two types, rural and urban (29). The rural outbreaks have been mostly in irrigated areas extending from the central valley of California to western Texas. One of the more recent epidemics occurred in the high plains of Texas in 1956; there were at least 250 cases. One characteristic of rural SLE is that it is frequently mixed with WE infections.

Notable epidemics of SLE in urban and sub-urban areas since the historic 1933 outbreak include the following:

Date	Place	Number of cases
1937-----	St. Louis, Mo-----	500
1954-----	Hidalgo County, Tex-----	1,000
1955-----	Calvert City, Ky. ¹ -----	13
1956-----	Louisville, Ky-----	110
1957-----	Cameron County, Tex-----	130

¹ Population 1,500.

Although all age groups are susceptible to the SLE virus, in many epidemics the incidence has been highest in individuals over 50 years of age. Mortality during recent years has ranged from less than 2 percent to 11 percent.

Current knowledge indicates that *C. tarsalis* is the principal vector of rural SLE in the west and *Culex pipiens-quinquefasciatus* the primary vector for the urban form of the disease in central United States. Several hundred virus isolations have been made from *C. tarsalis* in 8 States. Lumsden, in 1933, implicated *C. pipiens* as the vector of encephalitis in St. Louis (30); and SLE virus isolations were made from the *C. pipiens* complex during outbreaks

in Yakima Valley, Wash., 1942 (31); in Hidalgo County, Tex., 1954 (32); and in Calvert City, Ky., 1955 (33).

C. pipiens-quinquefasciatus mosquitoes are frequently referred to as "dirty water" breeders since they show a predilection for polluted water. Outbreaks of SLE in the lower Ohio Valley in 1955 were associated with heavy production of *C. pipiens* caused by improper disposal of industrial wastes (33). During the Louisville outbreak in 1956, excessive populations of these mosquitoes were produced from an estimated 20,000 to 25,000 street catch basins situated throughout the city.

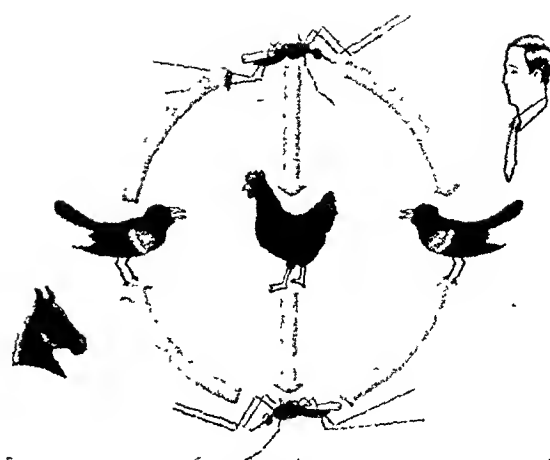

It is paradoxical that droughts and outbreaks of urban SLE seem to be related. Climatic conditions in the St. Louis area in 1933 were most unusual. According to official Weather Bureau records, the rainfall in St. Louis for the months of June, July, and August was the lowest in its history, since 1837 (34). It should be noted that a dearth of rainfall is not necessarily deleterious to the production of *C. pipiens*, a species that breeds prolifically in sewage disposal areas and other manmade breeding places which may receive an artificial supply of water.

Epidemiological studies have revealed that both wild and domestic birds are commonly infected with the SLE virus. Most of the evidence, however, is based on antibody studies rather than on virus recoveries. To date, the virus has been reported from only two birds in the United States, a mourning dove in California and a flicker in Kentucky (33).

Current Investigations and Control

Intensive investigations on mosquito-borne encephalitis are now underway in various sections of the United States. The primary purpose of these investigations is to acquire detailed information on the natural history of these viruses so that practical control measures can be developed. Some pertinent questions that need to be answered are: What causes the periodic epizootics and epidemics? Is each virus continuously present in an area or is it reintroduced? What is the most feasible approach to the control of encephalitis? What is the epidemic potential for the future?

In Florida, a total of 2,219 cases among horses and mules was reported by the U. S. Department of Agriculture for the 23-year period 1935-57. The largest number of cases (368) was reported in 1957. The disease has been reported in all but 2 of the 67 counties of the State, but the majority of cases have occurred in the fresh-water lake region of central Florida.

Infection chain of the mosquito-borne viral encephalitis.

cial habitats are sphagnum bogs and cedar swamps (24). In general, the distribution of major fresh-water swamps in this country coincides with the range of the EE virus and *C. melanura*, the principal area being the low-lying coastal plains.

Wild birds are considered to be natural reservoirs of the EE virus. During outbreaks of the disease, approximately one-half of the birds sampled may show immunity against EE, as evidenced by the presence of neutralizing antibody (26). Virus recoveries have been made from about 20 species of wild birds. Domestic fowl are not considered to be important reservoirs of the eastern virus.

A unique feature of the eastern virus is that it may cause clinical illness in birds, particularly confined ring-necked pheasants. Since 1938, when the virus was first isolated from the brains of pheasants reared on farms in Connecticut (16) and New Jersey (17), the disease has caused more than 100 outbreaks among pheasant flocks in 8 States, including 1 outbreak in Florida. An interesting epidemiological feature of the malady in pheasants was the finding that the virus can be transmitted mechanically from bird to bird during acts of feather picking and cannibalism, common vices among penned pheasants (18, 19).

Of the three encephalitis viruses, EE is the most virulent. Fatality averages about 90 percent for horses and 60 percent for humans. Approximately two-thirds of the human cases occur in children under 10 years of age. Of the survivors, most do not recover completely.

Recent studies on vectors of EE have implicated the bog mosquito *Culiseta melanura* as the primary vector for maintaining the basic infection chain in nature (bird-mosquito-bird). Proof is lacking, however, that *C. melanura* is responsible for human and horse outbreaks of EE. Certain other mosquitoes, such as *Aedes*, *Psorophora*, and *Mansonia*, are suspected vectors (20). *C. melanura* has been shown to be a laboratory transmitter of the EE virus (21), and 17 natural isolations have been made from pools of this species in Louisiana (22), New Jersey (23, 24), Massachusetts (25), and Alabama (personal communication from R. W. Chamberlain, Public Health Service, Montgomery, Ala.). This mosquito feeds extensively upon birds (24), but the extent to which it feeds on man and horses under natural conditions is unknown.

C. melanura is extremely selective in its breeding places and tends to choose secluded shady sites with cool and acid water in permanent fresh-water swamps. Some of its prin-

An abundance of summer rainfall seems to be a contributory factor in epidemics and epizootics of EE. This is exemplified by outbreaks in Massachusetts: In June and July 1938, the rainfall totaled 16 inches, and in August 1955, following hurricanes Connie and Diane, 17 inches occurred. Normal summer rainfall is 3 to 3.5 inches per month (27). Conversely, prevailing dry conditions tend to inhibit outbreaks. In 1957, when Massachusetts experienced an extreme summer drought, there were no verified clinical cases of EE in pheasants, humans, or horses (28).

St. Louis Encephalitis

St. Louis encephalitis is regarded by some as the most important mosquito-borne disease in

the United States. This type of encephalitis derives its name from the serious epidemic which was centered in St. Louis and St. Louis County, Mo., during the late summer of 1933. More than 1,100 human cases were reported in the city and county.

Distribution of the SLE virus is not so clearly delineated as that of the WE and EE types since the horse does not serve as a sentinel animal for SLE infections. In general, the virus occurs throughout the western and central States. An unusual record was obtained last summer, when the virus was recovered from the spinal fluid of a patient in Plant City, Fla. (personal communication from J. O. Bond, Florida State Board of Health, Jacksonville).

St. Louis encephalitis outbreaks appear to be of two types, rural and urban (29). The rural outbreaks have been mostly in irrigated areas extending from the central valley of California to western Texas. One of the more recent epidemics occurred in the high plains of Texas in 1956; there were at least 250 cases. One characteristic of rural SLE is that it is frequently mixed with WE infections.

Notable epidemics of SLE in urban and suburban areas since the historic 1933 outbreak include the following:

Date	Place	Number of cases
1937-----	St. Louis, Mo-----	500
1954-----	Hidalgo County, Tex-----	1,000
1955-----	Calvert City, Ky. ¹ -----	13
1956-----	Louisville, Ky-----	110
1957-----	Cameron County, Tex-----	130

¹ Population 1,500.

Although all age groups are susceptible to the SLE virus, in many epidemics the incidence has been highest in individuals over 50 years of age. Mortality during recent years has ranged from less than 2 percent to 11 percent.

Current knowledge indicates that *C. tarsalis* is the principal vector of rural SLE in the west and *Culex pipiens-quinquefasciatus* the primary vector for the urban form of the disease in central United States. Several hundred virus isolations have been made from *C. tarsalis* in 8 States. Lumsden, in 1933, implicated *C. pipiens* as the vector of encephalitis in St. Louis (30); and SLE virus isolations were made from the *C. pipiens* complex during outbreaks

in Yakima Valley, Wash., 1942 (31); in Hidalgo County, Tex., 1954 (32); and in Calvert City, Ky., 1955 (33).

C. pipiens-quinquefasciatus mosquitoes are frequently referred to as "dirty water" breeders since they show a predilection for polluted water. Outbreaks of SLE in the lower Ohio Valley in 1955 were associated with heavy production of *C. pipiens* caused by improper disposal of industrial wastes (33). During the Louisville outbreak in 1956, excessive populations of these mosquitoes were produced from an estimated 20,000 to 25,000 street catch basins situated throughout the city.

It is paradoxical that droughts and outbreaks of urban SLE seem to be related. Climatic conditions in the St. Louis area in 1933 were most unusual. According to official Weather Bureau records, the rainfall in St. Louis for the months of June, July, and August was the lowest in its history, since 1837 (34). It should be noted that a dearth of rainfall is not necessarily deleterious to the production of *C. pipiens*, a species that breeds prolifically in sewage disposal areas and other manmade breeding places which may receive an artificial supply of water.

Epidemiological studies have revealed that both wild and domestic birds are commonly infected with the SLE virus. Most of the evidence, however, is based on antibody studies rather than on virus recoveries. To date, the virus has been reported from only two birds in the United States, a mourning dove in California and a flicker in Kentucky (33).

Current Investigations and Control

Intensive investigations on mosquito-borne encephalitis are now underway in various sections of the United States. The primary purpose of these investigations is to acquire detailed information on the natural history of these viruses so that practical control measures can be developed. Some pertinent questions that need to be answered are: What causes the periodic epizootics and epidemics? Is each virus continuously present in an area or is it reintroduced? What is the most feasible approach to the control of encephalitis? What is the epidemic potential for the future?

Cause of Periodic Outbreaks

Current information suggests that epidemics and epizootics of mosquito-borne encephalitis are due to a fortuitous set of ecologic conditions, including high prevailing temperatures, heavy mosquito populations, and high rates of virus infections among an abundance of wild birdlife.

High sustained temperatures during the summer months seem to favor outbreaks of encephalitis. Normally the peak months for these outbreaks are July, August, and September. In mild climates, such as Florida and Texas, cases may occur as early as April, May, or June.

Many investigators believe that the most important basic factor in determining whether or not an epidemic would occur in an area is prevalence of the mosquito vector. There is much evidence that a rapid increase in vector populations is usually accompanied by a corresponding increase in virus infection among birds.

A large population of susceptible birds and efficient vectors in the vicinity of man and horses would set the stage for explosive outbreaks of encephalitis. Birds appear to be ideal natural hosts because, as Buescher points out, they are prolific and short-lived (35). This results in a rapid turnover of population with large numbers newly susceptible each year. Smaller birds and nestlings, which circulate high levels of virus in their blood, are probably more important than the larger and older birds in the transmission cycle. In a recent study, it was shown that *C. tarsalis* feeds much more readily on nestling birds than on adults of the same species (36).

Maintenance of Viruses

A major problem that still needs to be solved is how the viruses maintain themselves during the nonepidemic season. One leading theory is that they are harbored in overwintering mosquitoes; another possibility is that they are maintained by latent infections in birds. There is considerable evidence that both these survival mechanisms are involved. For example, the WE virus has been isolated from naturally infected *C. tarsalis* collected in Kern County, Calif., in all months of the year except Decem-

ber (37), and it can survive through the winter in experimentally infected *C. tarsalis* (38). Also, this virus has been isolated from *C. tarsalis* in Colorado in December (39). In support of the avian theory are laboratory studies showing that birds may have a recurrent viremia and persisting organ infection for 1 to 10 months after infection with the WE virus (40). The hypothesis that migratory birds annually reintroduce encephalitis into this country has fallen into disrepute. Results of recent studies by Kissling and co-workers on the EE virus indicate the presence of stationary foci of infection (41).

Control

At present, prevention of encephalitis consists of two principal approaches, immunization and mosquito control. Vaccination is recommended as a prophylaxis for equines, but human immunization is not considered economically feasible; furthermore, suitable vaccines for human use are now not available.

Employment of measures to minimize vector mosquito production in areas where encephalitis may be endemic or epidemic appears to be the most practical approach to prevention. Present knowledge indicates that control efforts should be focused on *C. tarsalis*, *C. pipiens quinquefasciatus*, and *C. melanura*. An alternative possibility, which needs further study, would be the control of avian reservoirs of the viruses.

Epidemic Potential

Because of the lack of specific therapeutic treatment and lack of suitable human vaccines, coupled with the apparent widespread infection among birds and mosquitoes, the encephalitis viruses have a high epidemic potential. Hence, it behooves all public health workers to keep well informed on the epidemiology of this group of diseases and to maintain continuous vigilance. It is hoped that the intensive investigations now underway will provide a practical answer for adequate protection against the mosquito-borne encephalitis infections.

Summary

During the past 25 years, severe epidemics of western encephalitis (WE) and St. Louis

encephalitis (SLE) have occurred throughout western and central United States, but to date no major human outbreaks of eastern encephalitis (EE) have been recorded.

Because of grossly inaccurate and incomplete reporting, the actual incidence of "infectious encephalitis" is unknown, but this disease is being recognized as an increasingly serious health problem in the United States.

Information accumulated regarding the natural history of the WE, SLE, and EE viruses indicates that wild birds, particularly small species and nestlings, are the principal reservoirs of infection, and mosquitoes the vectors. The basic infection cycle normally is limited to birds and mosquitoes, with humans and horses as incidental entries.

Primary vectors of encephalitis include *Culex tarsalis* for both WE and rural SLE in the west and the *Culex pipiens* complex for urban SLE in central United States. Definite knowledge regarding the vectors of EE is lacking, but current evidence implicates *Culiseta melanura* for maintaining the basic infection chain in nature (bird-mosquito-bird) and possibly *Aedes*, *Psorophora*, and *Mansonia* mosquitoes for transmitting the disease to horses and humans.

Epidemics appear to be due to a fortuitous set of ecologic conditions, including high prevailing temperatures, heavy mosquito populations, and high rates of virus infections among nestling and adult birds.

The only known possible approach to the control of encephalitis in the United States is one of prevention, the employment of measures to minimize mosquito production in areas where encephalitis may be endemic or epidemic.

Owing to the constant and serious threat of encephalitis epidemics, it behooves all public health workers to keep well informed on the epidemiology of this group of diseases and to maintain continuous vigilance.

EDITOR'S NOTE: Mr. Beadle in this paper omits from western and eastern encephalitis the term "equine" on the ground that in the light of present knowledge this designation is misleading.

Cancer Morbidity in the United States

IN 1938 the National Cancer Institute initiated a series of studies of morbidity from cancer which finally included 10 metropolitan areas scattered throughout the United States. Approximately a decade later, during 1948 and 1949, the study was repeated in the same areas.

Part I of this monograph, dealing with variations in the incidence of cancer by age, sex, race, geographic region, marital status, primary site, and histological type, was published in July 1955. This publication completes the analysis and combines the data contained in part I with that in part II. A discussion of intercity variation in cancer incidence has been added to part I. Part II compares the 10-city data with data from other sources and also deals with trends in cancer morbidity during the decade between the two surveys, the association of cancer incidence and income class, stage of disease at diagnosis, comparison of death certificates and case reports, and interpretation of the age curve of the incidence of cancer.

In 1947, out of every 100,000 residents of the 10 survey areas, 430 had cancer at some time during the year, in 319 cancer had been newly diagnosed, and 149 died of cancer. Compared with 1937, the prevalence rate was 26 percent higher, the incidence rate was 30 percent higher, and the mortality rate was 19 percent higher. Adjustment for the changed age composition of the population indicates a residual increase in reported illness from cancer of 10 percent for prevalence, 14 percent for incidence, and 3 percent for mortality.

The incidence of a number of specific forms of cancer is associated with socioeconomic status. The most consistent relationship observed is a relatively high rate of cancer incidence among members of the lower income classes. This type of association was clearly evident for the upper alimentary tract (lip,

mouth, pharynx, esophagus, and stomach), pancreas, respiratory system (larynx and lung), and cervix uteri. In contrast to findings for the upper alimentary tract, the incidence of cancers of the lower alimentary tract (large intestine and rectum) appears to be unrelated to income class. Similarly, in contrast to cancer of the cervix uteri, there appears to be no

Public Health

MONOGRAPH

No. 56

The accompanying summary covers the principal findings presented in Public Health Monograph No. 56, published concurrently with this issue of Public Health Reports. The authors are with the National Cancer Institute, National Institutes of Health, Public Health Service.

Readers wishing the data in full may purchase copies of the monograph from the Superintendent of Documents, Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Health Service. Copies will be found also in the libraries of professional schools and of the major universities and in selected public libraries.

Dorn, Harold F., and Cutler, Sidney J.: Morbidity from cancer in the United States. Public Health Monograph No. 56 (PHS Pub. No. 590). 207 pages. Illustrated. U. S. Government Printing Office, Washington, D. C., 1958. Price \$1.

association between income and the incidence of endometrial cancer.

Specific information on the stage of disease at diagnosis was available on 4 out of every 5 newly diagnosed cancer cases. Of those with a specified stage, 51 percent were reported to be localized at the site of origin, 27 percent with involvement of regional tissues, and 22 percent with remote or diffuse metastases.

In addition to the inherent metastatic potential of tumors, the accessibility of the organ of origin to direct examination is an important influence on the likelihood of discovering a neoplasm in an early stage of development. Sixty-two percent of cancers that originated in accessible sites were diagnosed while localized, compared with only 38 percent of cancers originating in inaccessible sites. However, when skin cancer, which generally does not spread to other organs, is excluded, the proportion of accessible cancer diagnosed while localized is reduced to 49 percent.

For a number of sites, the average age of patients diagnosed while the tumor was localized at the site of origin was definitely younger than the average age of patients who remained undiagnosed until after the extension

of the tumor to regional tissues or metastasis to remote organs. This was true for cancers of the ovary, uterus, and breast in women, and for cancers of the rectum in both sexes. It is possible that for these neoplasms the metastatic potential is greater in older than in younger women. However, it seems more likely that the difference in age between localized and metastatic tumors reflects the effect of delay in diagnosis. Thus, it appears that for cancers of the female reproductive system and the rectum the percentage of tumors diagnosed while localized is subject to improvement through screening programs, regular physical examinations, and increased alertness on the part of the layman and the physician.

In contrast to cancers of the aforementioned sites, patients with localized cancers of the stomach and lung tended to be older than those with regional or remote metastases. It is unknown whether rapidly metastasizing tumors of the stomach and lung tend to develop in younger people or whether the younger observed average age of patients with advanced neoplasms simply results from the fact that rapidly spreading tumors become symptomatic relatively soon after onset.

Public Health Service Traineeships

A total of 551 professional public health workers are attending school during the academic year 1958-59 on traineeships awarded by the Public Health Service under title I of the Health Amendments Act of 1956.

Public health nurses form the largest category receiving training, with sanitary engineers, health educators, and physicians next in order.

The list announced by the Division of General Health Services, Public Health Service, as of December 10, 1958, follows:

Nurses.....	245	Veterinarians.....	15
Sanitary engineers.....	62	Nutritionists.....	14
Health educators.....	48	Dentists.....	13
Physicians.....	45	Laboratory personnel.....	13
Sanitarians.....	39	Medical social workers.....	8
Others in sanitary field.....	16	Dental hygienists.....	5
Statisticians.....	16	Miscellaneous.....	12

publications

Proceedings of the National Conference on Hospital-Acquired Staphylococcal Disease. *PHS Publication (unnumbered)*; 1958; 213 pages.

Papers presented by the speakers and recommendations of the working delegates appear in these proceedings. Reviewing what is known about the infections, delineating areas that need additional investigation, and mapping plans for a practical attack on the problem, the publication provides extensive resource material.

The Summary Report of Discussion Groups in Section 2 is being reprinted. A limited number of copies of the proceedings and of the reprints of the discussion group summary are available from Chief, Technical Reports and Library; Communicable Disease Center, 50 Seventh Street, N.E., Atlanta 23, Ga.

Health Statistics From the U. S. National Health Survey. Concepts and definitions in the health household-interview survey. *PHS Publication No. 584-A3*; 1958; 29 pages; 30 cents.

Emphasizing the structure of the household interview, the first section discusses the questionnaire, the interviewer and respondent, and time references in the interview.

Concepts of morbidity (including unrefined data, sifting criteria, and diagnostic information), disability, and medical and dental care are explored in separate sections.

Definitions comprise the largest section of the book. They relate to general morbidity, disability, persons injured and accidents, hospitalization, medical and dental care, location of residence, and demographic, social, and economic terms.

The Missouri: Water and Land Development for the Nation. *PHS Publication No. 604*; 1958; by the Missouri Basin Interagency Committee; 32 pages; 55 cents.

A description of the Missouri River Basin Water Resources Development Program, this booklet discusses why it is needed, tells what

is being built and how it is being done, illustrates the benefits, explains the cooperative operation, and outlines what needs to be done to complete the development plan.

The aim of the booklet is to provide a nontechnical explanation to the general public of this development activity, which covers one-sixth of the Nation's area.

An Electron Microscopic Study of the Early Stages of Dentinogenesis. *PHS Publication No. 613*; by Marie U. Nylén and David B. Scott; 1958; 55 pages; 45 cents.

Reporting one of the first embryological studies made at the electron microscopic level, this book should attract the attention of teachers as well as researchers.

Structural changes undergone by a group of cells during their differentiation, the subsequent alterations that accompany the assumption of their tissue-forming activities, and the collagenous fibrillar elements that are elaborated as a result of cellular function are depicted.

CO and You. Carbon monoxide poisoning. *PHS Publication No. 611 (Health Information Series No. 91)*; 1958; 8 pages; single copies 10 cents; \$5 per 100. Discusses symptoms and dangers, possible sources, and first aid. Designed for educational efforts in accident prevention.

Highlights of Progress in Research on Neurologic Disorders, 1957. *PHS Publication No. 597*; 1958; 16 pages; 15 cents.

Selected items on program developments and research studies conducted or supported by the National Institute of Neurological Diseases and Blindness, Public Health Service, during 1957 are compiled in four categories: basic research developments, collaborative and cooperative programs, advances in neurosurgery, and progress in individual disease categories.

Highlighted are advances relating to diagnosis of eye disorders, surgical treatment of temporal lobe epilepsy, biochemical findings pertaining to multiple sclerosis, cerebral palsy and parkinsonism, basic research relating to the regeneration of nerve tissue, improvement of a brain tumor detection device, and knowledge of the structure, function, and chemistry of the brain.

Selected References on Cardiovascular Disease. An annotated bibliography for nurses. *PHS Publication No. 472 (Public Health Bibliography Series No. 15)*; 1958; 72 pages; 30 cents.

A timesaving guide for nurses seeking information for their own and their patients' use, this completely revised bibliography supersedes the 1956 edition.

References are arranged in sections according to the main types of cardiovascular disease and to other major aspects such as public health and rehabilitation. A selection of films and other audiovisual aids is included. Annotations are designed to assist the nurse in gauging the usefulness of each listed item.

Insects That Carry Disease. *PHS Publication No. 594 (Health Information Series No. 90)*; 1958; 11 pages; single copies, 10 cents, \$5 per 100. Warns against houseflies, cockroaches, mosquitoes, fleas, and ticks as vectors of disease. Recommends measures for their control.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared with Federal support.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Office of Information, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

ENDEMIC FLUOROSIS AND ITS RELATION TO DENTAL CARIES¹

By H. TRENDLEY DEAN, *Dental Surgeon, United States Public Health Service*

INTRODUCTION

The first thorough study of mottled enamel, that of Black (1) and McKay (2) at Colorado Springs and including the Pike's Peak watershed, reported as early as 1916 that, in regard to caries, the teeth of these Colorado children co-

munities where endemic I wrote of the difficulty of teeth and stated that, though in non-endemic areas teeth are eventually lost because of the hypoplastic tooth structure.

Workers in other countries have reported various aspects of this phenomenon. In the western part of the Japanese archipelago, endemic areas in the Prefecture of Shima, and Aichi, 12 of the 47 prefectures. In an English abstract of his work, he stated that "It is also remarkable that the number of observations is comparatively small among the number of observations is not stated in the abstract."

Ainsworth has commented on the prevalence of caries among children in the town of Bridge, Essex County, England. The Committee for the Investigation of the Dental Research Council, this year, has examined 4,000 children in the public

RELATION BETWEEN THE AMOUNT OF DENTAL CARIES (PERMANENT TEETH) OBSERVED IN 7257 SELECTED 12-14 YEAR OLD WHITE SCHOOL CHILDREN OF 21 CITIES OF 43 STATES AND THE FLUORIDE (F) CONTENT OF PUBLIC WATER SUPPLY

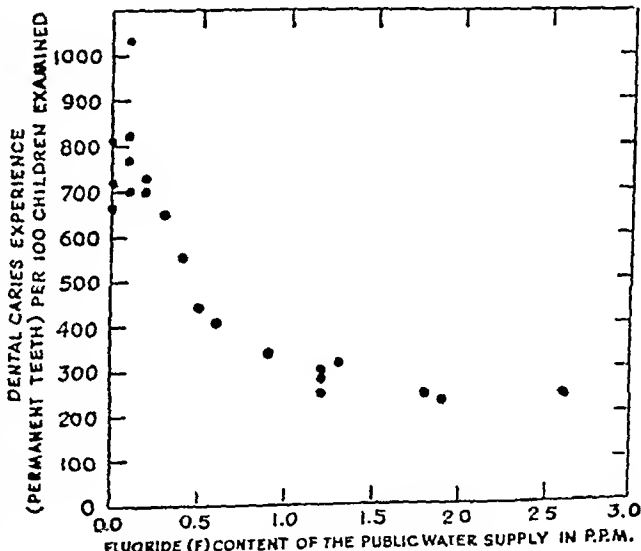

FIGURE 2

AUGUST 19, 1938, pp. 1443-1452

After verifying the relationship between the natural occurrence of fluorides in drinking water and the reduction in dental caries, Dr. H. Trendley Dean concluded that the "possibility of controlling dental caries through the domestic water supply warrants thorough epidemiological-chemical study." Figure 2 in an article that followed (August 7, 1942, pp. 1155-1179) provides the basis for present-day fluoridation.

Poliomyelitis Vaccination

SURGEON GENERAL LEROY E. BURNEY

IN 1958 there was more paralytic poliomyelitis in the United States than in 1957. The rates for paralytic cases were highest in 1-year-olds, and more than half of all paralytic cases occurred in children under 5 years of age.

Despite the high susceptibility of the Nation's preschool children, about a third have had no poliomyelitis vaccine. The total unvaccinated population under 40 years of age, including children and young adults, is more than 40 million.

These salient facts about the progress of vaccination against poliomyelitis were the subjects of a daylong discussion in Washington, D. C., in early December 1958. The meeting was called by the Public Health Service and was attended by representative State and city health officers and health educators and officials of the American Medical Association, the American Academy of Pediatrics, the Association of State and Territorial Health Officers, the National Conference of State Health Educators, the National Health Council, the National Foundation, the Advertising Council, Inc., and the Pharmaceutical Manufacturers Association.

The group agreed that the story of the Salk vaccine during the past 3 years is a truly remarkable one. More than 50 million persons have been vaccinated, and the incidence of poliomyelitis has dropped gratifyingly. Seldom, if ever, in the history of public health have so many persons taken advantage so quickly of a major preventive health measure. Seldom has there been a greater mobilization of health and medical resources, or a more intensive and sustained effort by official and voluntary organizations to accomplish a health purpose.

We have at hand a highly effective vaccine.

The 1958 poliomyelitis experience, to be described in the Communicable Disease Center's 1958 Poliomyelitis Surveillance Report, has provided additional evidence to support this statement.

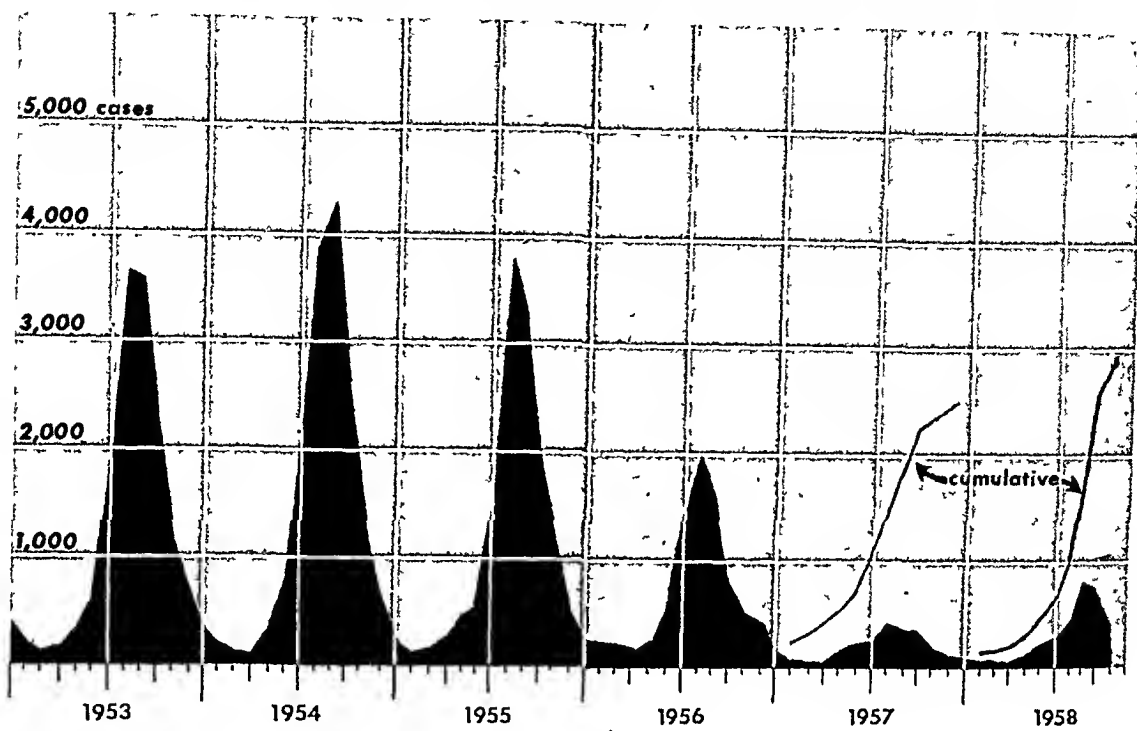

Yet the task remains to carry further the work of immunization. Although the Salk vaccine is not a 100 percent preventive and although the available data suggest that poliovirus continues to circulate even in well-vaccinated communities, it is evident that much of the paralytic poliomyelitis that occurred in 1958 could have been prevented if more persons had been vaccinated. It is equally clear that, by pushing forward with vaccination programs now, much can be done to reduce the number of paralytic cases that will otherwise occur in 1959 and subsequent years.

To translate what we know about a problem into effective action to solve it is, of course, one of the principal and never-ending challenges of society. Every health administrator is aware of the twin needs: to dispel ignorance and to overcome apathy.

Why have vaccinations lagged in the past 6 months? What means can be used to stimulate more people to seek vaccinations? These two questions were the chief subjects discussed at the Washington meeting.

The participants agreed that the primary responsibility for reaching the unvaccinated remains, as it always has, with the local community. Much has been done that can contribute to the accomplishment of the remaining task. The public is now widely informed about the vaccine, and professional people have gained valuable experience. These advantages, however, only partially offset the fact that the

Monthly Paralytic Poliomyelitis Incidence, 1953-1958

people who now remain unvaccinated are largely those who are difficult to reach with any health program. To get them vaccinated will require "face to face" campaigns under the leadership of local groups.

Surveys have demonstrated that many of the unvaccinated are in the lower socioeconomic groups. Reports from three of the 1958 epidemic areas stress this point. It is borne out, as well, by a sample survey conducted in Atlanta by the Public Health Service's Communicable Disease Center. It would be a mistake, however, to attribute the lag solely to economic reasons. Many communities, through local medical societies or public agencies, have offered vaccine free or at minimal cost during these past 3 years and found too few takers. Such factors as educational status, accessibility of clinics, simple fear of the needle, the human fault of procrastination, and, of course, indifference and apathy—all have a bearing. These and other problems are discussed in a paper by Rosenstock, Derryberry, and Carriger in this issue of *Public Health Reports*, pp. 98-103.

Undoubtedly the relative importance of the factors that interfere with acceptance of poliomyelitis vaccination varies from community to community. It is therefore important for each community to determine for itself what its chief problems are and how they relate to the current vaccination status in the various geographic sections of the city, such as census tracts or school districts. The resulting information then needs to be used to tailor the community's vaccination program to fit the local situation.

Professional health workers need not be reminded of how the process of acquiring this information can be used to enlist the active participation of physicians, agencies, and organizations in the vaccination program. It has been demonstrated many times that such groups work much more effectively throughout a program if they are consulted and utilized in the factfinding stage. By this device they are made to feel keenly their responsibility to do something about the findings that their studies reveal.

At the Washington meeting, the Public

Health Service announced that it was willing to help in this aspect of local community drives by lending to communities some of the technicians who carried out the Atlanta survey. I am glad to repeat that offer here.

The emphasis on local community responsibility is also explicitly set forth in recommendations unanimously adopted by the House of Delegates of the American Medical Association at the annual meeting on December 4, 1958. A happy coincidence of dates enabled us to provide the representatives at our meeting with a copy of the AMA resolution.

In brief, the recommendations are that (a) each physician assume responsibility for making sure that all members of the families he sees are fully vaccinated; (b) that State medical societies work with State health departments to bring county medical societies together with health departments to work out vaccination programs; and (c) that county medical societies meet with local health departments to survey local problems and devise ways to meet local situations.

In discussing the role of the local community with respect to poliomyelitis vaccination activities, I do not mean to suggest that the Public Health Service will not continue its efforts. We shall, of course, continue our surveillance and reference diagnostic services and continue to

offer assistance when epidemics threaten. In promoting vaccinations, we shall continue to conduct a program of public information and education through the States and in cooperation with national organizations.

We have asked again and have been assured of the assistance of the Advertising Council in a national campaign, to begin in the spring, of newspaper, radio, and television reminders of the importance of poliomyelitis vaccinations.

All the national organizations represented at our meeting have indicated that they will continue their national programs and will urge their State and local affiliates to do all within their power to make community drives a success. The National Health Council has also offered its assistance in working with other national organizations.

The new element introduced at the Washington meeting, in other words, was not a shift in the relative responsibility assumed by national, State, and local organizations but rather a shift in the way these efforts would be channeled. Until now, programs have been aimed principally at the general public. It is proposed now that in addition we seek to pinpoint our targets, finding as precisely as possible what segments of the population in each community have not been reached, and devising programs to meet their special needs.

Zero Tolerance for Aramite Established

The Food and Drug Administration has ruled that no residue of the pesticide Aramite is permissible on fruit and vegetables in interstate commerce. The new order, effective December 24, 1958, rescinds the previously established tolerance of 1 ppm.

The action was based on data from animal feeding studies, submitted by the manufacturer, which show that Aramite when fed at levels as low as 500 ppm causes cancer in dogs.

At the request of the manufacturer, and as provided by law, an advisory committee of scientists was nominated by the National Academy of Sciences and appointed by the Food and Drug Administration to consider the data from the feeding studies. The committee recommended the zero tolerance for Aramite.

Analysis of research on the social and psychological factors which influence people to accept or reject poliomyelitis vaccination suggests that people who are currently incompletely vaccinated can best be reached through personal, face-to-face contacts.

Why People Fail to Seek Poliomyelitis Vaccination

IRWIN M. ROSENSTOCK, Ph.D., MAYHEW DERRYBERRY, Ph.D.,
and BARBARA K. CARRIGER, B.A.

EPIDEMIOLOGICAL investigations of the 1958 outbreaks of poliomyelitis add to the growing body of evidence that Salk vaccine is safe and effective in preventing the disease. The major proportion of cases, particularly the paralytic, are occurring among incompletely vaccinated individuals. Thus the prevention of such epidemics as occurred in 1958 will not devolve primarily upon technical development of preventives. Rather, prevention will require increasing the number of people who protect themselves and their families through vaccination. Public health workers desiring to bring about such action can be more effective if they know why people fail to accept poliomyelitis vaccination, their motivations in rejecting or accepting it, the conditions under which they will respond to appeals for action, and the communication channels through which they get health information.

To provide such information quickly, the Public Health Service, through the regional office organization, recently asked States and

universities to supply information obtained from systematic studies which would help to identify (in terms of age, education, income, and other factors) segments of the population that have been hard to reach for vaccination, and which would help to explain why people accept or fail to accept poliomyelitis vaccinations.

In addition to the formal inquiry, the literature on these topics was searched independently.

Although little time was available for gathering data in preparation for a national meeting to consider the problem, more than 40 research activities on poliomyelitis vaccination were identified. Seventeen of these were found to bear directly on the question of why people accept or fail to accept vaccination for themselves and their families. Of the 17 studies, 13 were reviewed; 4 were unavailable. Seven of the 13 were discarded because of methodological limitations in their design or because they could not be properly evaluated.

The six remaining studies (1-6) are methodologically sound and report findings which have implications for planning poliomyelitis vaccination programs. These studies contribute to our understanding of why people accept or reject vaccination. However, except for the Clausen (2) and Deasy (3) reports, which rep-

The authors are in the Division of General Health Services, Public Health Service. Dr. Rosenstock is chief, and Mrs. Carriger social psychologist, of the Behavioral Studies Section. Dr. Derryberry is chief of Public Health Education Services.

resent different analyses of the same data, the studies were independently done, so that the relationships among the findings are not always clear. We shall attempt, therefore, to crystallize these relationships by analyzing the findings according to one set of explanatory concepts. The interpretations presented here, however, are not fully supported by adequate data in all cases. Additional studies of the explanatory concepts will be required to assess the validity of our interpretations.

From an analysis of the six studies, it would appear that two broad classes of factors determine the decision to participate in vaccination programs. These are personal readiness factors and social and situational factors.

Personal Readiness Factors

The factors of personal readiness include the motives, attitudes, and beliefs of individuals which affect their willingness to take voluntary action with regard to their health. Hochbaum (7) has described the importance of these factors in guiding the decision to obtain chest X-rays. In connection with poliomyelitis vaccination, three components of a person's readiness to seek vaccination can be identified: the extent to which he believes he may be susceptible to the disease, the seriousness with which he regards the consequences of getting the disease, and his conception of the safety and effectiveness of the vaccine.

Perceived Susceptibility

It would appear that a basic determinant of the decision to seek vaccination is the extent to which the individual believes that he is susceptible to poliomyelitis, or, for children, the extent to which the parent believes that his child is susceptible.

In Glasser's report of the study made for the National Foundation for Infantile Paralysis (4), the absence of perceived susceptibility is cited as 1 of the 2 principal barriers to the decision to obtain vaccination. Merrill and his associates (5) show that poliomyelitis tends to be regarded as a disease affecting only children, which may account for the failure of some adults to accept vaccination. The authors suggest that the establishment of vaccination

priority groups tended to reinforce this perception among leading people that those included in the first priority group were the only ones who needed vaccination. The familiar picture of the child on crutches may also have reinforced the belief that poliomyelitis is a disease of children.

The failure to believe that one is susceptible to poliomyelitis may be a widespread problem. In the National Foundation for Infantile Paralysis study (8), 72 percent of the young adult sample believed that poliomyelitis had been nearly brought under control.

It must be stressed that this variable, perceived susceptibility, refers to the beliefs of people and not to objective facts about incidence. It is known that behavior is determined more by one's beliefs about reality than by reality itself, and that people vary markedly in their interpretations of reality.

Perceived Seriousness

Even when an individual feels he is susceptible to poliomyelitis (or believes that his child is), he will not act on his feeling unless he also believes that his becoming ill would have serious repercussions on his life. Here again it is the belief rather than the reality which is the important determinant of the decision. -

While the data on seriousness are not as clear-cut as those on susceptibility, the studies by the National Foundation for Infantile Paralysis and Merrill and his co-workers suggest the importance of this factor in determining one's decision concerning vaccination. In the former study, it is shown that twice as many men as women in a nationwide sample believed that poliomyelitis in adults is milder than in children, and half as many men in the sample had been vaccinated. The latter study shows that the over-40 age group may not see poliomyelitis as constituting a serious problem for adults, and additional data suggest that poliomyelitis is considered to be milder in adults than in children.

Safety and Effectiveness

One's decision to accept vaccination for one's self and one's family is a function not only of the perceived likelihood of contracting the disease and the perceived seriousness of the disease

should it occur, but it is also a function of the kinds of beliefs one has about the safety and effectiveness of vaccination in reducing susceptibility and seriousness.

However concerned one is with poliomyelitis, if he thinks the vaccine is unsafe or ineffective, he will not accept vaccination. In the three studies reviewed which were conducted in connection with the field trials of 1954, questions of safety and effectiveness are frequently mentioned as a factor limiting decisions to participate (2,3,6). However, in Glasser's 1957 study (the most recent of the several reviewed), it is shown that such fears have largely been dispelled and no longer seem to be an important factor limiting acceptance of vaccination. It is certainly possible, however, that in specific groups this factor may still be important.

The three variables, perceived susceptibility, perceived seriousness, and beliefs about vaccination, define the kinds of personal factors that influence a decision relative to vaccination. But there is reason to believe (although the authors of the studies reviewed do not discuss this point) that the decision is determined not only by the kind of beliefs one has but by other factors as well.

Again and again the studies reviewed list procrastination, forgetfulness, neglect, apathy, carelessness, and laziness among the factors influencing the decision to vaccinate. These terms are not useful since they neither define a dynamic process nor suggest ways of overcoming the problem. We believe that these terms may be synonyms for one of two kinds of processes.

Clausen (9) reports data from California which suggest that there is a social class influence on behavior which is somewhat independent of the three beliefs described above. He shows that even among mothers who are generally favorable to vaccination those with much education and married to white collar workers were much more likely to have their children vaccinated than those with little education and married to blue collar workers. The extent to which such a social class influence operates independently of the kinds of beliefs described above must await detailed study of that question.

It is also possible that "procrastination,"

"apathy," "laziness," and the like reflect insufficient amounts of readiness to obtain poliomyelitis vaccinations.

It has been noticed that a great many people appear to have minimal motivation with regard to poliomyelitis. Glasser, for example, reports that by and large "people were failing to take advantage of the vaccine for themselves and their children, not because of specific resistance to it, but rather because of lack of definite, positive influences which might direct them to a clinic or doctor's office for inoculations" (4).

Limited data suggest that many people may already share the necessary beliefs, but not in sufficient degree. It is likely that those people with more than minimal motivation have already been vaccinated.

Social and Situational Factors

The personal readiness factors influence the voluntary decision to seek vaccination. However, the studies reviewed suggest as well that a variety of situational and social conditions may be effective in stimulating people to seek vaccination even in the absence of appropriate kinds and degrees of personal readiness.

Two components of the social and situational factors may be identified: social pressure and convenience.

Social Pressure

Clausen, Deasy, Glasser, and Merrill (2-5) all observe that vaccinated persons are more likely than unvaccinated persons to report discussion of vaccination with friends, in groups such as the PTA, or with physicians. Despite certain difficulties in interpreting this finding, it has at least been demonstrated that considerably more communication and interaction occurs among people who have taken action than among those who have not.

The individual's decision to seek vaccination may be determined by the social pressures applied by persons who are important to him. Belcher (1) shows that a greater proportion of Negroes than whites participated in a vaccination program in two Georgia communities. He suggests the importance of the fact that Negro school teachers urged the program among their pupils as enthusiastically as they could. There

is even a hint that the activities of some may have bordered on coercion. Negro ministers, both on and off the pulpit, urged vaccination. Public health physicians and nurses, presumed to be of fairly high status in the Negro community, also urged the people to seek vaccination.

Data presented by Glasser suggest that the physician will have a highly important role in stimulating people to be vaccinated. More than 90 percent of his adult sample looked to the physician as the principal source of information on poliomyelitis. Moreover, an overwhelming majority of unvaccinated persons reported that they would seek vaccination if their physician recommended it, and 80 to 90 percent of this group reported having a regular physician.

Convenience

Included within the notion of convenience is the distance one has to travel to obtain vaccination, the hours at which it is available, the cost of vaccination, and the acceptability of the facilities in which vaccination is performed. For any individual with a given degree of readiness to be vaccinated, the ultimate decision will be facilitated the more convenient, simple, and inexpensive the action is.

In explaining the higher participation rate of Negroes than of whites in the communities he studied, Belcher suggests the importance of the fact that vaccinations were administered at and by the local health department, a facility more widely known and accepted among Negroes than whites, that vaccination was free, and that more school buses were provided to take Negro children to the clinic for vaccination than to take white children.

Readiness and social factors may operate with a degree of independence of each other or they may interact. However, when the personal readiness to seek vaccination is weak, we would not expect the individual to act unless the social and situational forces impinging on him were strong. On the other hand, when relevant social factors are weak or absent, vaccinations would be sought only by persons with considerable personal readiness.

The evidence to date suggests that, among the currently unvaccinated, personal readiness to

obtain poliomyelitis vaccination is so weak that rather strong social supports may be needed to modify their behavior in the short run. Educating for increased personal readiness can probably be effective only in the long run.

Obviously, the use of social forces in urging poliomyelitis vaccination entails working with local groups, often in face-to-face contacts. Deasy, Glasser, and Merrill have made this point explicitly, and Belcher has made it implicitly.

Each of the studies reviewed uncovered ignorance or misinformation among the people interviewed, and especially among those who have not been vaccinated. Clausen, Deasy, Glasser, Merrill, and Weiss show that acceptance of poliomyelitis vaccination is closely related to socioeconomic status, primarily education and occupation or income. The majority of the studies reviewed here offer evidence that the groups hardest to reach (the poorly educated and the nonwhite) will have to be approached personally rather than through mass means of communication. This conclusion is supported by research on communications performed on other subjects.

In the following paragraphs, only a few communication studies will be mentioned, although the bibliography is extensive. The role of television can only be referred to; standard books on communications research do not yet include much on the new medium.

Communications Research

It is known that different groups are differently exposed even to the most ubiquitous media. Lazarsfeld and Kendall (10) have shown that the lower educational groups do not read newspapers, magazines, and books to the same extent as do groups with more education; they differ little in exposure to movies and radio. However, even when groups are exposed to the same medium, they may attend to and learn different things from the same material.

Schramm and White (11) showed that with respect to newspaper reading, lower educational groups tended to read news of crime, corruption, disaster, and sports, whereas the more educated tended to read news of public affairs, economics, science, and social affairs.

Moreover, in a study performed for the National Association of Science Writers (12), it was clearly shown that the extent to which one could recall having learned any science or health information from newspapers, magazines, television, or radio was closely related to amount of education. Thus, of a group with less than high school education, more than one-third could recall no health or science information from these media, whereas of the group with high school education, only 11 percent were similarly unable to recall science or health information. At the higher educational levels, virtually everyone was able to recall science and health information from these sources.

Some of the data reported in the poliomyelitis studies support this trend. Belcher found that the nonwhites in his sample obtained their information on poliomyelitis and vaccination from personal sources (teachers, children, public health officials), while whites tended to get their information through impersonal sources. Similarly, Deasy showed that while all women in her sample had been exposed to an identical brochure, which had been brought home by their children, on the 1954 field trials, and while practically all women in the sample had been exposed to daily papers which were featuring intensive coverage of the field trials, the women differed in knowledge and acceptance of the program, acceptance being associated with amount of education.

Katz and Lazarsfeld (13) report that people who are reached by educational programs through the mass media are very largely those who do not need the education. Those who do need the education tend to stay away. In their words, "Those groups which are most hopefully regarded as the target of the communication are often least likely to be in the audience. Thus, educational programs . . . are very unlikely to reach the uneducated; and goodwill programs are least likely to reach those who are prejudiced against another group" (13a).

It is not to be denied that the mass media have, and always have had, an important role in communication. However, the poliomyelitis and communication studies reviewed here suggest that the assets and liabilities of the traditional approach should be considered in the

light of the particular needs that face us in attempting to reach the lower income family, the family with little formal education, and the nonwhite family.

In this context, Merrill and his co-workers, in discussing people who have little money and little formal education, have said, "It appears that there is need for a change in target and methods if we are to reach this group effectively with health education" (5).

In a similar vein, Glasser states, "Informal communication—getting people to talk about vaccination—would appear to be the most direct method of accelerating the vaccination program" (4).

Summary

A person's beliefs about his susceptibility to poliomyelitis, about the severity of the disease, and about vaccination comprise the major components of his readiness to take action. On the other hand, social forces, including factors of pressure and convenience, are important in guiding the decision to be vaccinated or not.

The data reported tend to suggest that social class membership may affect decisions to be vaccinated and that personal readiness for poliomyelitis vaccination may be weak in those who are currently incompletely vaccinated. If this is so, the social factors would have to be stressed in order to insure more widespread acceptance of vaccination.

In considering the approaches that may be made to reach groups in an attempt to stimulate greater acceptance of vaccination, one is struck with certain serious limitations of the traditional approach of mass media of communication. It would appear that personal contacts with members of the so-called hard-to-reach groups may be required to stimulate increased acceptance of poliomyelitis vaccination.

film

Use of Anticoagulants in Rodent Control

35-mm. filmstrip, color, sound, 9½ minutes, 76 frames. 1958.

Audience: Federal, State, local, and other health personnel engaged in rodent control.

Providing a comprehensive description of how anticoagulants are employed to kill rodents, this filmstrip shows the advantages of these poisons compared with other poisons. It lists the forms and types of anticoagulants available. It describes the various baits and tells how to prepare them, shows the

containers and how to place the poisons to get the most efficient kill. Precautionary measures to be used in handling these materials are emphasized.

This film may be obtained on LOAN from the Communicable Disease Center, Public Health Service, 50 7th Street NE., Atlanta 5, Ga., or by PURCHASE from United World Films, Inc., 1445 Park Avenue, New York 29, N. Y.

Legal note . . . Liability for Air Pollution

Res ipsa loquitur doctrine held applicable in suit for damages resulting from fluoride poisoning allegedly caused by defendant's aluminum reduction plant; defendant's evidence of reasonable care held insufficient to require finding as a matter of law that inference of negligence had been overcome. *Reynolds Metals Company v. Yturvide*, 258 F. 2d 321 (9th Cir., June 5, 1958).

The plaintiffs claimed they were poisoned by fluorides originating from the plant of the defendant, the Reynolds Metals Company. Their injuries were found by a jury to have been caused by excessive emission of fluorides by the defendant's plant. On appeal by the defendant the court of appeals, sustaining the verdict for plaintiffs, held that the defendant's evidence of reasonable care in operation of the plant was not sufficient to rebut the presumption that the excessive emission of fluorides was attributable to defendant's negligence.

The defendant operated an aluminum reduction plant in Troutdale, Oreg. In December 1946, shortly after operations began, the plaintiffs moved to a farm about 1 mile from the plant. For a period of about 4 years, a daily average of 2,800 pounds of fluoride was discharged into the atmosphere from the plant, running as high as 3,900 pounds daily in 1 month. In November 1950, when an improved system was installed, the fluoride discharge was reduced to a daily average of 643 pounds.

Although there was no proof of the quantities of fluorides which reached the plaintiffs' land, the court found that the fluorides emitted by defendant's plant were toxic, and it was conceded by the defendant that the fluorides escaping from its plant were poisonous in excessive amounts. The plaintiffs showed that the fluoride effluent reached their property and settled on it, that it was absorbed by vegetables, which were eaten by plaintiffs, that it etched the glass in their home, and that it was presumably inhaled by them. Evidence was also adduced that the plaintiffs' health improved when they moved away from the vicinity of the plant.

The defendant contended that (a) the proof was insufficient to demonstrate that the plaintiffs' injuries were caused by fluorides escaping from the plant and (b) there was no evidence of negligence or breach of duty by the defendant.

With respect to the first contention, the court held that on the basis of the evidence presented the

jury was warranted in finding that the plaintiffs' injuries were caused by the fluorides emitted by the defendant's plant which found their way to the plaintiffs' property. Although evidence was presented by the defendant to show that only a small concentration of fluorides could have reached the plaintiffs, the court ruled that the fact that they suffered fluoride poisoning supported the finding that an "excessive amount" of fluoride, sufficient to cause such poisoning, was cast upon the plaintiffs' property from the defendant's plant.

The plaintiff was unable, however, to specify any particular acts of negligence by the defendant which brought about the injury and was compelled to rely on the legal doctrine of "*res ipsa loquitur*" (the thing speaks for itself) under which the facts of the occurrence warrant the inference of negligence.

Since the defendant's evidence was to the effect that, despite the large amounts of fluorides it admitted escaped into the air, no significant concentrations of fluorides were produced in localities near the plant, the trial court charged the jury that it was not to be expected that in the ordinary course of events the fluorides emitted by the plant would cause injury in the absence of negligence of the defendant. The court of appeals held that a finding that excessive amounts of fluorides were deposited on plaintiffs' property (a permissible inference from the facts) from the plant whose construction, operation, and maintenance was under the exclusive control of the defendant could reasonably be accepted as circumstantial evidence of negligence.

The court rejected the defendant's argument that this holding resulted in the application of a rule of absolute liability. Although the defendant's evidence tended to show that reasonable care had been exercised to control the amount of fluorides emitted by its plant, the court pointed out that such evidence did not preclude the jury from rejecting the defendant's version of the facts nor from finding that the defendant was in fact negligent.

New laboratory procedures are used for evaluating critical dosage, bait refusal, and speed and variability of action of five poisons against three rodent species. Warfarin is not excelled by other compounds tested, but some others are about equal to it against some species.

Laboratory Studies of Five Anticoagulant Rodenticides

WAYLAND J. HAYES, Jr., M.D., Ph.D., and THOMAS B. GAINES, B.S.

EARLIER studies on warfarin have emphasized the difference between the newer, anticoagulant rodenticides and the older, quick-acting poisons (1). It was evident at the beginning that laboratory tests used for quick-acting rodenticides were not applicable to the newer poisons without modification. Hence, development of a suitable laboratory method for rapid evaluation of the slow-acting rodenticides was an important part of the present studies. The procedures devised, as well as the results obtained with respect to required dosage, bait refusal, and speed and variability of action, are reported in detail.

Materials and Methods

All wild rodents tested were caught by hand in the field and then held in the laboratory on a diet of laboratory chow (A) for a minimum of 2 weeks before testing. During each test, the rodents were kept separately in cages of the Army Medical School type. They were offered free choice of (a) unpoisoned, ground labora-

tory chow and (b) yellow cornmeal (maize) containing an appropriate concentration of the rodenticide under test. Water was available at all times. Yellow cornmeal was chosen as the food in which to offer the poison because it has proved to be the most generally acceptable, inexpensive bait under field conditions. Laboratory chow was used as the poison-free food because it was the food to which the rodents were conditioned before the tests began and because it is as similar as is practically possible to the mixed diet which rodents receive in nature. Providing the two foods simulates field conditions, as it is generally impractical under field conditions to offer poison to rodents in the same kind of food as that to which they are accustomed. In fact, an effort should be made to offer a bait which the animals will prefer to their ordinary food.

Figure 1, part a, shows cups for offering a choice of food in place at the back of a cage. These cups, with special lids to minimize spillage, are available commercially. They are satisfactory, but experience has shown that wild rats overturn them occasionally. Spring clips were designed to hold the cups firmly in place (fig. 1, parts b and c). These clips, made without special tools from 24-gauge galvanized sheet metal, can be bolted to the back of each cage. The food cups can be easily removed

Dr. Hayes is chief of the Toxicology Section, and Mr. Gaines is a pharmacologist with the Technical Development Laboratories, Technology Branch, Communicable Disease Center, Public Health Service, Savannah, Ga.

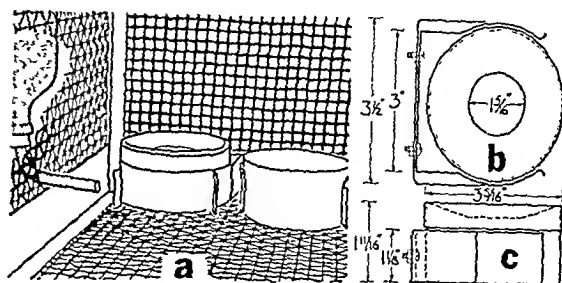

from the clips for weighing, but rodents cannot move them.

These cups, the smallest commonly available from dealers, are too large to use with mice since straggle animals frequently get into them, while mice weakened by poison cannot reach the food at all and are thus starved. Cups made from 2-ounce ointment cans proved satisfactory for mice. A hole seven-eighths of an inch in diameter was cut in the center of the metal lid, and the top portion of the lid was then depressed in a conical form similar to that of the larger, commercial models shown in the figure. Special holders for the small cups were not necessary even for wild mice. A disk of $\frac{1}{4}$ -inch mesh hardware cloth was put in each cup to prevent mice from scratching food out. As an added precaution, fresh paper was used in the tray of each cage so that any spilled bait could be detected.

The following rodenticides were studied: warfarin, 3-(*d*-acetonylbenzyl)-4-hydroxycoumarin; coumachlor, 3-(*d*-acetonyl-4-chlorobenzyl)-4-hydroxycoumarin; Pival, 2-pivalyl-1,3-indandione; PMP, calcium salt of 2-isovaleryl-1,3-indandione; and Diphacinone, 2-diphenylacetyl-1,3-indandione (*B-F*). Each compound was tested against adults of one or more of the following species: the Norway rat, *Rattus norvegicus*; the roof rat, *Rattus rattus*; and the house mouse, *Mus musculus*. A short supply of animals prevented testing coumachlor against mice or Diphacinone against roof rats or mice.

The dry, poisoned baits were prepared by mixing appropriate amounts of the rodenticide into the bait with an ordinary kitchen-type electric food mixer. For low concentrations of poison (50 ppm or less), the technical grade compound was weighed out carefully on an analytical balance and then, with a mortar and pestle, thoroughly mixed with cornstarch in the proportion of 1 part rodenticide to 99 parts cornstarch by weight. The amount of this rodenticide-cornstarch concentrate required to give the desired concentration of poison in a selected weight of finished bait was weighed out and mixed thoroughly with about one-fourth the necessary weight of cornmeal. The remainder of the cornmeal was then added and mixed to give the final concentration of poison

Figure 1. Equipment for offering a choice of baits to caged rodents.

Part a, food cups held in place by metal clips (cover of one cup removed). Part b, top view of metal clip and food cup. Part c, end view of same clip with food cup in place.

to be tested. For the higher concentrations of rodenticide (100 ppm or more), the procedure was the same except that the proportion was 1 part rodenticide to 19 parts cornstarch. Each separate mixing with the cornmeal required at least 15 to 20 minutes. Coarse, degerminated cornmeal of a quality suitable for cooking was used in all the tests.

Each rodenticide was tested in several of the following concentrations, which form a geometric progression with a factor of one-half: 800, 400, 200, 100, 50, 25, 12.5, 6.3, 3.1, and 1.5 ppm. Chemical analyses showed that it was possible to obtain these concentrations with an error of 0.5 ppm or less. Ten rodents (5 males and 5 females, when possible) were usually used for each test; more than one test was frequently made, especially at the lower dietary concentrations. Each rodent was offered the poison (as well as poison-free food) for a maximum of 40 days. Surviving animals were maintained on laboratory chow until they died or until their survival was assured. The time of death was recorded in all instances.

During the tests, the intake of poisoned bait and of poison-free food was recorded daily for each animal. The animals were weighed once a week. These measurements made possible the calculation, on a milligram per kilogram basis, of the total dosage of rodenticide ingested by each rodent. They also made possible direct comparison of the amount of poisoned bait and of poison-free food taken by each rodent. Bait refusal is conveniently expressed as the average percentage of the total daily

diet during the exposure period which was poison free. As already mentioned, this percentage was intentionally suppressed by offering the poison in an attractive bait. However, the choice of diet used in the test permits rodents to refuse poison completely (bait refusal=100 percent) without undergoing any hunger.

Under practical conditions of use, it is characteristic of poisoning by anticoagulant rodenticides that most of the animals die relatively soon after the first one, but a few linger on for many days especially when the poison is fed at a low concentration. (The initial delay is explained by the pharmacological action of these compounds.) Values skewed in this way tend to be normalized by logarithmic transformation. Therefore, the logarithms of the survival times were used to calculate the geometric mean and 95 percent confidence limits. The antilogarithms of the resulting values were then plotted (together with the observed values) against the concentration of rodenticide in the bait. In all instances, the calculations were based solely on animals which died. However, in those instances in which one or more animals survived the test, the upper 95 percent confidence limit was not plotted because in this situation it is not realistic.

The critical dosage is defined as the smallest average dosage killing a species so rapidly that the upper 95 percent confidence limit for that and all higher average dosages is 45 days or less. (Usually, the critical dosage was identical to the smallest average dosage which killed all rodents tested.) The dietary level of poison consumed by those rodents which received the critical dosage is designated the critical concentration.

The average bait refusal of rodents offered four times the critical concentration is selected as the value for comparison of one species with another and of one poison with another. The factor of 4 is used so that comparisons may be made for dietary levels suitable for field use. It has been observed, within the geometric progressions of dosages studied, that a factor of 4 compensates adequately for irregularity in consumption of bait and other ill-defined variables which characterize the use of rodenticides in the field. Thus, a factor of 2 is too small,

and a factor of 8 is unnecessarily large. For the same reason, the geometric mean for time-to-kill (in days) for rodents offered four times the critical concentration is selected as a comparative value for the speed of action.

The variability of action is defined as the difference (in days) between the geometric mean and the upper 95 percent confidence limit of the time-to-kill for rats fed four times the critical concentration. This method of expressing variability of response gives practical information about the period necessary to kill a species with a particular poison. The variabilities of dosage and bait refusal tend to be correlated; however, they are of less practical interest and are not presented in this paper.

Results

The results in regard to dosage are presented for all compounds and all species tested in table 1. Corresponding results on bait refusal and speed of action are given in figure 2. Some indication of the variability of action of each poison also may be inferred from the figure.

The data in table 1 indicate that the critical dosage is truly characteristic of the action of a particular poison in a particular species. For example, the critical dosage of warfarin for wild Norway rats was 4.2 mg./kg., corresponding to a concentration of poison of 12.5 ppm; yet even over the wide range of concentration of poison of 1.5 to 50 ppm the average dosage showed the narrow range of 2.3 to 6.8 mg./kg. The critical dosage of warfarin for the roof rat was 18.1 mg./kg., a value distinctly different from that for the Norway rat.

The dosage of any of the rodenticides tested necessary to kill the three common commensal rodents is small; however, as shown in table 1 and in figure 2, the three species differ strikingly in their response to the rodenticides. In general, the Norway rat was most susceptible, as judged by dosage and survival time, and the roof rat was least susceptible. Furthermore, the roof rat tended to show greater variability of response than the Norway rat. The house mouse resembled the Norway rat in susceptibility but the roof rat in variability. Thus, the results determined for one species cannot be applied with precision to another.

NOTE: Critical dosages, as defined in text, are in boldface type.

There is evidence, both from a high degree of bait refusal and from an increase in bait refusal with increasing concentration, that PMP is detected by wild Norway rats and by mice. There is some evidence, from an increase in bait refusal with increasing dietary concentration on the first day of exposure, that both species of rats may detect the higher concentrations of warfarin. However, all three species tended to adjust to the flavor of the rodenticides so that secondary bait refusal was not significantly greater and was occasionally slightly less than the corresponding primary bait refusal. (Secondary bait refusal, also called "bait shyness," consists in a learned response frequently based

on illness induced by a poison.) Thus, the anticoagulants contrast strongly with the fast-acting rodenticides, which lead to more serious primary bait refusal and especially to almost complete secondary bait refusal. This observation does not contradict the fact that, as rodents became progressively poisoned with anticoagulants, they ate less and less food of both kinds.

Within groups in which all animals died, special analysis was made of the animals which survived more than 14 days. Study of the individual records showed that, with rare exceptions, all animals of the three species which survived more than 2 weeks took substantial

								1.8-13.2	4.3	10	100

NOTE: Critical dosages, as defined in text, are in boldface type.

amounts of poison; in fact, their longer survival permitted them to take, on the average, slightly greater total dosages than corresponding rodents which died sooner. Further, most of the rats and mice which survived more than 2 weeks took poison promptly when it was first offered. The few exceptions were refusals of PMP for 21 days or more, with the result that the animals did not receive an adequate dosage. It must be concluded that the unusually long survival periods of a few rodents exposed to effective bait concentrations usually were caused by unexplained properties in the metabolism of the individual animals and not by their failure to ingest poison.

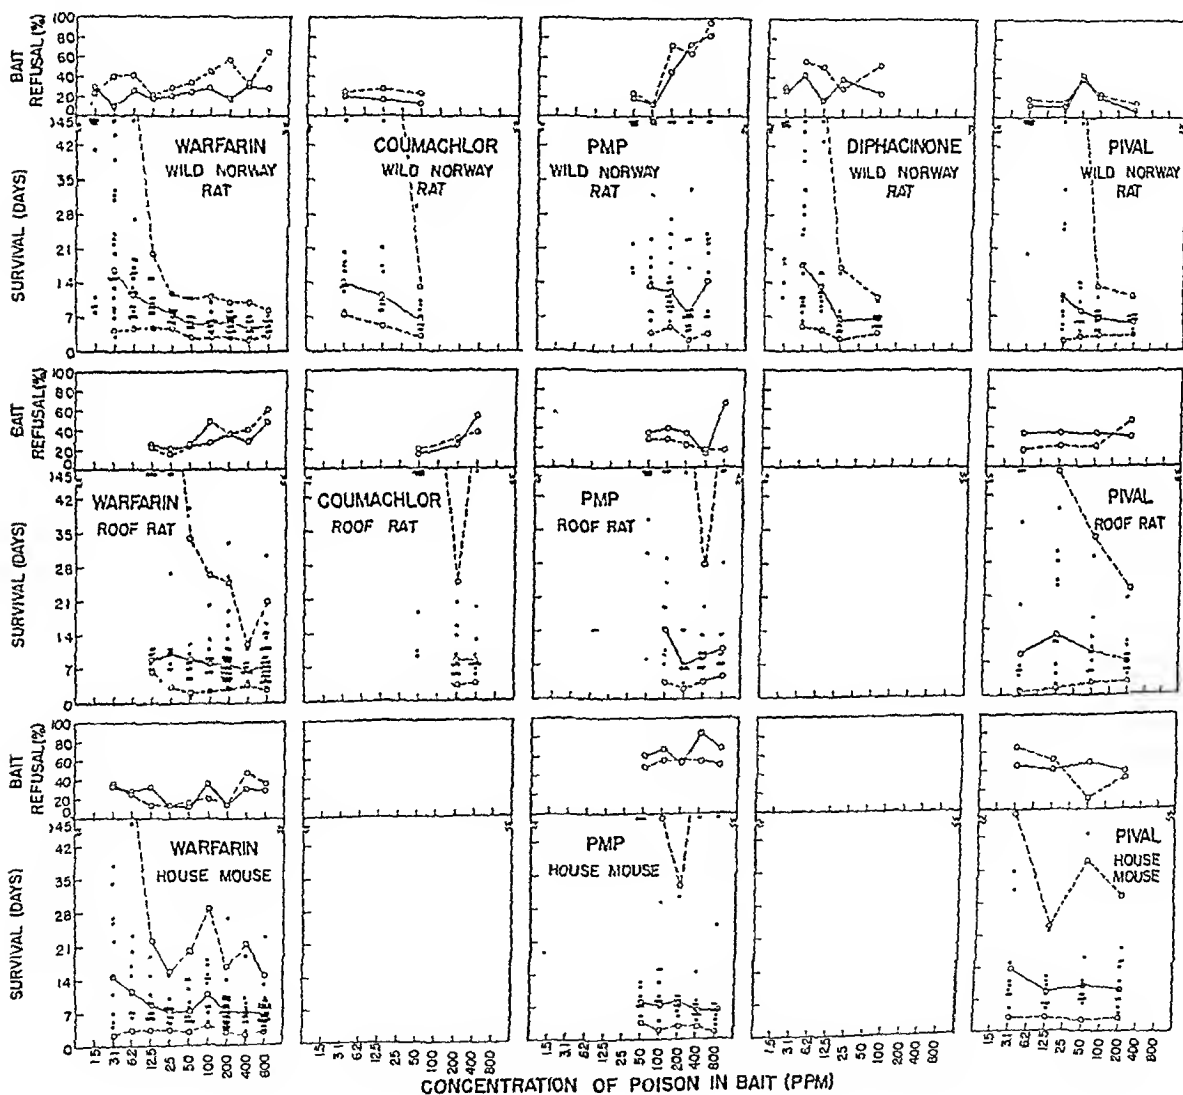

The time necessary to kill the first rat in a group was remarkably similar for the poisons studied irrespective of the concentrations at which they were fed. This is explained by the mode of action of the compounds. Death is the result of hemorrhage following the loss of "prothrombin" activity in the blood. A minimum period of time is required for the activity to be reduced and then for adequate hemorrhage to occur. This is true even in animals which suffer cerebral hemorrhage as well as those which die in the usual way from shock following more extensive bleeding at less critical sites. It appears from figure 2 that the average survival time of wild Norway rats fed

warfarin is not shortened to a practical degree by increasing the concentration of poison in bait above the minimum necessary for effective control. The same is probably true of other rodents and other anticoagulants; however, application of the principle to roof rats fed warfarin was obscured because of the great variability in the response of that species and in

other instances because few of the bait concentrations tested were above that which is minimal for control.

Analysis of the data revealed no differences in susceptibility based on sex in any of the three species studied. None of the females was pregnant. Earlier tests have shown that pregnant animals exhibit an increased susceptibility (1).

Figure 2. Bait refusal and survival time of rodents offered unpoisoned food and various concentrations of rodenticides in bait.

BAIT REFUSAL (percentage of total food intake which was unpoisoned): Dashed line, first day of experiment. Solid line, entire experiment.

SURVIVAL TIME: Dots, survival time for each

rodent. Open circles connected by solid line, geometric mean for the time of death of rodents that died; open circles connected by dashed line, 95 percent confidence limit.

Table 2. Critical dosage, bait refusal, speed of action, and variability of action characteristic of anticoagulant rodenticides

Species and rodenticide	Critical dosage (mg/kg.)	Critical concentration (ppm)	Bait refusal (percent)	Mean speed of action (days)	Variability of action (days)
<i>Wild Norway rat</i>					
Warfarin.....	4.2	12.5	25	5.8	5.1
Coumachlor.....	9.0	50.0	¹ 12	¹ 6.1	¹ 6.8
PMP.....	>64.0	>400.0	² 82	² 14.1	² 38.0
Diphacinone.....	3.1	12.5	22	6.3	4.4
Pival.....	10.3	50.0	7	5.7	5.0
<i>Roof rat</i>					
Warfarin.....	18.1	50.0	36	8.0	15.6
Coumachlor.....	>112.5	>400.0	² 54	² 8.1	² 12.4
PMP.....	>256.0	>800.0	² 64	² 10.4	² 13.0
Pival.....	17.0	50.0	30	7.4	14.7
<i>House mouse</i>					
Warfarin.....	5.5	12.5	12	7.7	12.4
PMP.....	>292.0	>800.0	² 68	² 6.3	² 17.3
Pival.....	4.3	3.1	42	8.6	14.5

¹ Determined at the critical concentration because no test was run at four times the critical concentration.

² Determined at the highest dosage tested because a dosage satisfying the definition of critical dosage was not found.

NOTE: For each characteristic, a low value is favorable.

Of the several poisons tested, only warfarin was tested against Wistar strain albino Norway rats, with the same experimental procedures. The results (tabulations not shown) were so very similar to those for the wild Norway rat that for practical purposes they could be substituted for them.

A few new observations on pathological changes caused by warfarin supplement those reported earlier (1). A very few rodents poisoned by warfarin show paralysis of the hindquarters for a variable period before death. In every instance encountered so far, this sign of illness has been explained by the finding at autopsy of limited hemorrhage in the central nervous system. A few other rodents die rapidly without the development of paralysis as the result of more massive cerebral hemorrhage.

Mice show a distinctly different pathological condition from that observed in the two species of rats. Slightly more than half of 105 mice examined showed a profuse, thin, serosanguineous exudate into the pleural cavity. Both the character and location of this exudate differ from anything consistently seen in rats.

The results of this study, summarized in table 2, appear to justify the following conclusions.

The performance of warfarin against the commensal rodents was not excelled by the other anticoagulant compounds tested. Diphacinone was about as good as warfarin against wild Norway rats. Pival was about equal to warfarin against roof rats and mice but, like coumachlor, somewhat inferior against wild Norway rats. In comparison with the other rodenticides tested, PMP was distinctly inferior against all three species of commensal rodents.

Discussion

The method of laboratory testing described is adapted especially to the bioassay of rodenticides in instances in which both the toxicity and the acceptability of the material are under study. Use of the method for estimating proper concentrations of slow-acting poisons against a given species of rodent should obviate field testing of inappropriate concentrations.

Several papers dealing with testing of anticoagulant rodenticides have been published (2-12). However, we believe that the method described here yields more complete and more practical information than do earlier methods.

Laboratory tests in which the rodents are fed

poison on alternate days only were considered. Norway rats fed warfarin on alternate days survived slightly longer than those fed the same concentration of the poison *ad libitum* because there was a delay in acceptance of the poisoned food when it was offered on alternate days. Crabtree (2) and Bonnet and Gross (6), in tests with warfarin against Norway rats, found that the result was the same whether the rats were fed the poison *ad libitum* or on alternate days. On the other hand, *Rattus hawaiiensis* survived twice as long when fed warfarin on alternate days as when fed *ad libitum* (6). In any event, when poison is offered on alternate days only, the test is complicated by baiting problems so that it becomes more difficult to know which variables are being measured.

Every effort should be made to determine rodenticide dosages which are effective and, at the same time, as cheap and safe as possible. The use of unnecessarily high dosages may compensate in part for careless mixing of the bait, poor bait distribution, and inferior technique generally, but adds to the expense and to the hazards inherent in the use of rodenticides.

In one of the original studies (13) on the analogs of 3, 3-methylene bis(4-hydroxycoumarin), the compound now known as warfarin was shown to have less activity than some of the other compounds when tested against rabbits. When many of the analogs were tested later against Norway rats, warfarin proved to be the most promising of the group. Since species differences do exist, it appears quite likely that, if the analogs were tested systematically against the roof rat, a poison more nearly suited to that species might be found.

Summary

A new laboratory method was devised for the rapid evaluation of multiple-dose, slow-acting rodenticides with respect to required dosage, bait refusal, and speed and variability of action. With this method, it was found that, in general, wild Norway rats are most susceptible and roof rats least susceptible to each anticoagulant compound tested. Wild mice tend to resemble Norway rats in susceptibility, but they resemble roof rats in the high variability of response. The performance of

warfarin was not excelled by the other anticoagulant compounds tested, although coumachlor, Diphacinone, and Pival were each about equal to warfarin against 1 or 2 species. PMP was distinctly inferior in performance. A short supply of animals prevented testing coumachlor against mice or Diphacinone against roof rats or mice.

Specialized Training Courses in Environmental Health

The following courses are scheduled for March 1959 by the Robert A. Taft Sanitary Engineering Center in Cincinnati, Ohio:

March 2-13. Basic Radiological Health. Fundamental technical knowledge needed for radiological health work, with stress on basic nuclear physics and chemistry. Prerequisite for several other courses.

March 2-13. Water Quality Management: Sanitary Engineering Aspects. Intensive training for sanitary engineers and others active in administration of water-quality management programs. Biological, chemical, and bacteriological phases included. Assignment to discussion panels made prior to the course on the basis of experience and interest.

March 16-20. Physical Analysis of Atmospheric Particulates. Emphasis on properties and physical behavior of particles and methods of sampling and evaluation. Laboratory exercises used in application of techniques.

March 16-25. Environmental Health Aspects of Nuclear Reactor Operations. Introduction to environmental health and safety aspects of nuclear reactor operations, especially off-site problems. Includes 3-day tour of reactor and waste disposal facilities at Oak Ridge National Laboratory, with lectures by ORNL personnel. Prior completion of basic radiological health course required.

March 23-27. Analysis of Atmospheric Inorganics. Broad, technical coverage of qualitative and quantitative analysis of pollutants, with emphasis on applicability and limitations of present methods. Includes laboratory practice.

Address applications to the Chief, Training Program, Robert A. Taft Sanitary Engineering Center, Public Health Service, 4676 Columbia Parkway, Cincinnati 26, Ohio, or the medical director in a regional office.

Ecology of Foxes and Rabies Control

DAVID E. DAVIS, Ph.D., and JOHN E. WOOD, Ph.D.

A 5-year study of fox populations in the southeastern United States was undertaken to provide information applicable to the prevention of rabies. The research was designed to accomplish at least six objectives: to estimate numbers of foxes, to determine reproduction and death rates, to examine the extent of movement, to determine the prevalence of rabies in a random sample of foxes, to evaluate procedures for controlling their numbers, and to suggest possible trends in fox populations in the future. Results of the investigation, presented in detail in a series of papers in specialized journals (1-6), are here summarized and interpreted from the public health point of view.

The research was conducted in Georgia, Florida, and South Carolina, with Thomasville and Newton, Ga., as bases. This area was chosen for several reasons. First, rabies has occurred in these States for many years. Second, vegetation is typical of a great region from Virginia to Texas and thus findings should have wide applicability. Third, the Communicable Disease Center of the Public Health Service had in this area a laboratory which would provide certain services.

The basic philosophy of the research was that foxes are an integral part of the biological economy and should not be exterminated even if this

were feasible. It was believed, however, that their numbers should be held below a density at which rabies will occur and that control activities should keep the population below this threshold.

Census and Vital Data

The first step was to estimate numbers of foxes. A standard procedure of setting traps which permitted calculation of a simple relative census was developed (1). A number of traps were set according to specific rules. The traps were placed along dirt roads at intervals of 0.2 mile and examined each morning for 7 days. The proportion of stations that caught 1 or more foxes in 7 days was calculated (2). Thus, one trapping area might have a value of 0.15 and another of 0.30. These proportions are only relative measures. They simply indicate differences in number of foxes caught; they do not reveal absolute numbers of foxes. To determine absolute numbers of foxes, rather elaborate and expensive procedures are necessary (3). Fortunately, in most practical work a relative method is sufficient to indicate changes.

Since the number of foxes caught depends on movement as well as abundance, the trapping proportions can be used for comparisons of abundance only during periods when movements are constant (as measured by tracking patterns) or between areas of similar habitat. From several lines of evidence it seems clear that greatest movement occurs in the fall in this region. In six areas foxes were trapped in summer after the young were at large and again in the fall. The proportion of stations catching foxes was 0.09 in the summer and 0.18 in

Dr. Davis is associate professor, division of vertebrate ecology, Johns Hopkins University School of Hygiene and Public Health, Baltimore, Md. Dr. Wood, formerly research associate in the division, is now associate professor at Jacksonville University, Jacksonville, Fla.

The research reported here was conducted under Grant E1040 from the National Institutes of Health, Public Health Service.

Population index (proportion of trap stations catching foxes) before, during, and after a specified number of foxes were removed by trapping, five counties in Georgia.

WHITE AREAS: Periods during which foxes were removed by trapping. FIGURES IN WHITE AREAS: Number of foxes removed.

7 of these no positive fox was found in one trapping period when samples of from 9 to 83 foxes per county were examined. In the other 3 counties, 3.5 percent of 28, 11.3 percent of 62, and 8.8 percent of 147 foxes were positive for rabies.

These results demonstrate clearly that the detection of rabies in foxes by trapping on a sampling basis is not a sufficiently sensitive technique to be useful in predicting a rabies out-

break. The basic problem, of course, is that rabies occurs at a high prevalence in a few small areas. Thus, while in a large area only 3 percent of the trapped animals may have detectable virus, there may be many positive foxes localized in a few small habitats. Detection of rabies in foxes is very difficult under these circumstances.

The next step in the search for an indicator of future epidemics was to examine the density

the fall, but most of the increase in the index was due to increased travels of the foxes within their home range (3,5). In three large areas where movements were known as a result of capturing, marking, and releasing foxes, an increase in the number caught occurred in October and November.

The rate of increase of a population must be known in order to appreciate the efficacy of a reduction procedure or the recovery of a population after a natural calamity. Our research found that gray foxes averaged 4.5 embryos per female, that 96 percent of the females bred successfully, and that parturition occurred primarily in March and April (4). From these results we estimate that a population of 100 foxes in March will produce about 215 pups at birth. (We found no intra-uterine mortality.)

The rate of decrease of a population is equally important in evaluating numerical changes. To determine the mortality rate of foxes, a method of estimating age by tooth wear was developed (4). This permitted calculation of probability of dying from the age composition of various samples, using certain well-known assumptions. From these results it was found that the annual probability of dying is about 0.5 (annual death rate per fox=1.3). The life expectancy of an adult fox is 1.5 and that of a pup is about 0.9 years.

These mortality rates are surprisingly high, but they are coupled with a high rate of reproduction to produce a high proportion of young foxes in the population. In five areas in Georgia, Florida, and South Carolina, in which foxes were trapped in the winter, the percentage of foxes less than 1 year old varied from 48 to 61, and only 4 percent were more than 3 years old. The important conclusion here is that the fox population is essentially an annual crop. Control procedures and conclusions about prevalence of virus must recognize this situation.

Precise data on movement of foxes are difficult to obtain, but the question was explored by trapping foxes, tattooing a number in their ear, and releasing them in the expectation that some would be caught again and thus reveal some information about their movements. From the results it was clear that some foxes avoided recapture, but 56 were captured again. More

than half of these were recaptured within a mile of the point of release. An aspect of considerable importance is the tendency of foxes to remain together in groups, presumably familial (3). These groups disperse in early fall, and this dispersal apparently sets the stage for high mortality of pups.

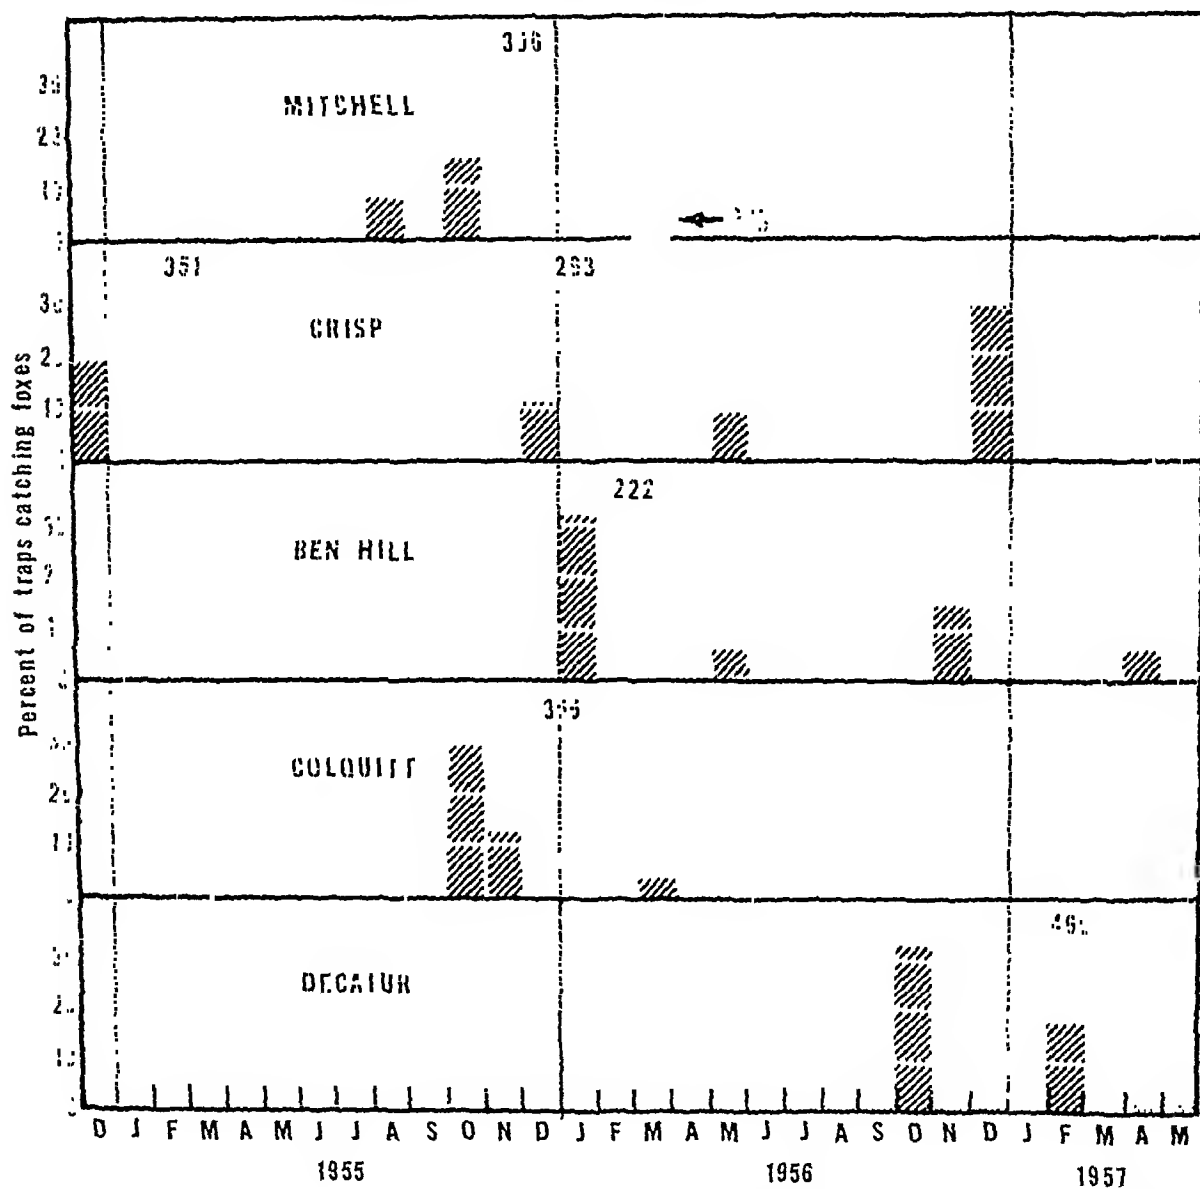

The relation of abundance of foxes to type of habitat is crucial to understanding current distribution and predicting future trends. Detailed analysis of trapping results shows clearly that foxes are most abundant in areas supporting cultivation (2). The population indexes were: cultivated areas, 0.22; savannah pine, 0.15; woods, 0.06. The agricultural trend in recent years has been from cultivated areas to woods (for pulp and timber) and pasture. This change greatly reduces the suitability of the area for foxes and should result in a decline in numbers.

Rabies Virus Prevalence

The prevalence of the rabies virus in the fox population was determined by examination of all fox heads from certain areas. This work was done at the Communicable Disease Center laboratory at Newton, Ga., under the general direction of Dr. Ernest Tierkel. Of 1,026 foxes, 32, or 3.1 percent, were found positive for rabies by virus isolation techniques (6). No statistical difference in prevalence between gray and red foxes was apparent, for 2 of the 117 red foxes were positive. None of the 299 raccoons or 215 opossums trapped was positive, but 1 of 89 bobcats and 1 of 144 skunks were positive.

The prevalence of the rabies virus differed, of course, from place to place. The data were analyzed to see whether the results could be useful in predicting an outbreak of rabies. The only practical geographic unit for this analysis was the county. In 5 counties that had not reported rabies in either man or animals for many years, none of the 133 foxes was positive. In 2 counties 2 rabid foxes were reported after an absence of reported rabies for 5 years, but examination of 93 foxes in these counties caught in 9 periods revealed no positive foxes. Ten counties had regularly reported rabies in humans or livestock for several years, but in

Population index (proportion of trap stations catching foxes) before, during, and after a specified number of foxes were removed by trapping, five counties in Georgia.

WHITE AREAS: Periods during which foxes were removed by trapping. FIGURES IN WHITE AREAS: Number of foxes removed.

7 of these no positive fox was found in one trapping period when samples of from 9 to 83 foxes per county were examined. In the other 3 counties, 3.5 percent of 28, 11.3 percent of 62, and 8.8 percent of 147 foxes were positive for rabies.

These results demonstrate clearly that the detection of rabies in foxes by trapping on a sampling basis is not a sufficiently sensitive technique to be useful in predicting a rabies out-

break. The basic problem, of course, is that rabies occurs at a high prevalence in a few small areas. Thus, while in a large area only 3 percent of the trapped animals may have detectable virus, there may be many positive foxes localized in a few small habitats. Detection of rabies in foxes is very difficult under these circumstances.

The next step in the search for an indicator of future epidemics was to examine the density

the fall, but most of the increase in the index was due to increased travels of the foxes within their home range (3,5). In three large areas where movements were known as a result of capturing, marking, and releasing foxes, an increase in the number caught occurred in October and November.

The rate of increase of a population must be known in order to appreciate the efficacy of a reduction procedure or the recovery of a population after a natural calamity. From these results we estimate that a population of 100 foxes in March will produce about 215 pups at birth. (We found no intra-uterine mortality.)

The rate of decrease of a population is equally important in evaluating numerical changes. To determine the mortality rate of foxes, a method of estimating age by tooth wear was developed (4). This permitted calculation of probability of dying from the age composition of various samples, using certain well-known assumptions. From these results it was found that the annual probability of dying is about 0.5 (annual death rate per fox=1.3). The life expectancy of an adult fox is 1.5 and that of a pup is about 0.9 years.

These mortality rates are surprisingly high, but they are coupled with a high rate of reproduction to produce a high proportion of young foxes in the population. In five areas in Georgia, Florida, and South Carolina, in which foxes were trapped in the winter, the percentage of foxes less than 1 year old varied from 48 to 61, and only 4 percent were more than 3 years old. The important conclusion here is that the fox population is essentially an annual crop. Control procedures and conclusions about prevalence of virus must recognize this situation.

Precise data on movement of foxes are difficult to obtain, but the question was explored by trapping foxes, tattooing a number in their ear, and releasing them in the expectation that some would be caught again and thus reveal some information about their movements. From the results it was clear that some foxes avoided recapture, but 56 were captured again. More

than half of these were recaptured within a mile of the point of release. An aspect of considerable importance is the tendency of foxes to remain together in groups, presumably familial (3). These groups disperse in early fall, and this dispersal apparently sets the stage for high mortality of pups.

The relation of abundance of foxes to type of habitat is crucial to understanding current distribution and predicting future trends. Detailed analysis of trapping results shows clearly that foxes are most abundant in areas supporting cultivation (2). The population indexes were: cultivated areas, 0.22; savanna pine, 0.15; woods, 0.06. The agricultural trend in recent years has been from cultivated areas to woods (for pulp and timber) and pasture. This change greatly reduces the suitability of the area for foxes and should result in a decline in numbers.

Rabies Virus Prevalence

The prevalence of the rabies virus in the fox population was determined by examination of all fox heads from certain areas. This work was done at the Communicable Disease Center laboratory at Newton, Ga., under the general direction of Dr. Ernest Tierkel. Of 1,026 foxes, 32, or 3.1 percent, were found positive for rabies by virus isolation techniques (6). No statistical difference in prevalence between gray and red foxes was apparent, for 2 of the 117 red foxes were positive. None of the 299 raccoons or 215 opossums trapped was positive, but 1 of 89 bobcats and 1 of 144 skunks were positive.

The prevalence of the rabies virus differed, of course, from place to place. The data were analyzed to see whether the results could be useful in predicting an outbreak of rabies. The only practical geographic unit for this analysis was the county. In 5 counties that had not reported rabies in either man or animals for many years, none of the 133 foxes was positive. In 2 counties 2 rabid foxes were reported after an absence of reported rabies for 5 years, but examination of 93 foxes in these counties caught in 9 periods revealed no positive foxes. Ten counties had regularly reported rabies in humans or livestock for several years, but in

Developments in nuclear science in the past decade have demonstrated many ways of putting radiation to use in solving classic problems in such fields as hydraulics, water quality, insect control, food preservation, and air pollution.

Applications of Radiation in Sanitary Engineering

D. A. PECSOK, M.S., H. P. KRAMER, M.S., and D. W. MOELLER, Ph.D.

DURING the past decade the sanitary engineer has frequently assisted in solving problems associated with environmental surveillance of radioactive materials and their management and disposition. Often his studies of such problems have indicated beneficial uses of these materials. For example, studies of specific radionuclides contained in radioactive wastes have provided information on ground-water flow. Similarly, application of water treatment methods to decontamination of radioactive liquid wastes has demonstrated mechanisms of water coagulation and softening.

Encouraged by such results, the sanitary engineer in more recent years has been making direct applications of radioactive materials to the solution of classic problems. Although use of radionuclides in sanitary engineering is still far from routine, a sizable number of applications have been reported and others are in prospect.

Hydraulics

Traditionally, flow characteristics imposed by pipes, tanks, and other boundary conditions are determined by use of a stable tracer material such as sodium chloride or fluorescein dye. Such material does not always yield measurements sufficiently sensitive for accurate tracing

of flow paths. On the other hand, radionuclides, evaluated for use under widely varying conditions, provide a highly sensitive technique for this purpose (fig. 1). No single radionuclide has proved ideal for all purposes, selection depending on several key factors:

1. Half-life of the radionuclide. It should be sufficiently long for practical application and sufficiently short for safe disposal.
2. Suitability for measurement by laboratory or field equipment.
3. Safety of personnel conducting the study and others who may be exposed.
4. Physical, chemical, and biological compatibility with the fluid.

For convenience in reviewing the various hydraulics studies of radioactive tracers, the following broad groupings have been made.

Pipe Flow

Radionuclide tracers for measuring fluid flow in pipes have found wide application in the pe-

The authors are with the Training Program, Robert A. Taft Sanitary Engineering Center, Public Health Service, Cincinnati, Ohio. Mr. Pecsok is assistant chief of Radiological Health Training Activities; Mr. Kramer is chief of the Training Program; and Dr. Moeller is chief of Radiological Health Training Activities.

of foxes in relation to prevalence of rabies virus. The results in 24 locations showed no obvious relation between our measure of fox abundance and prevalence of rabies in the foxes. In 11 places where the prevalence varied from 2 to 33 percent, the abundance index (proportion of trap stations catching foxes) varied from 0.10 to 0.51. In 13 locations where no virus was demonstrated, the index varied from 0.06 to 0.40. Actually, there were significantly more captures in localities with recently reported rabies (0.29) than in those without recently reported rabies (0.22).

From this examination we conclude that neither the detection of virus in foxes nor the density of population of foxes is practical as a predictive measure. We thus accept the reporting of cases of rabies in animals and humans as the most promising method of maintaining surveillance of rabies, and we suggest greater emphasis on completeness and accuracy of reporting.

Evaluation of Control Methods

The next question for our research was, what are the most practical and most effective means of reducing fox populations? It is generally recognized that the best way ecologically to control a population is by manipulation of the habitat. Data summarized above suggest that the trend in the southeastern United States from small fields to forests or pasture will produce a reduction in foxes. Fortunately, this trend is expected to continue, but no other feasible habitat change is apparent.

The only alternative to habitat manipulation is killing foxes. Use of poisons should be rejected at once because it is nonselective. Trapping is feasible, and this method has been used for many years. Its effectiveness, however, needs more examination.

Records are available in five counties for the fox population before, during, or after a reduction program by conventional trapping methods (see chart). In four counties (Mitchell, Ben Hill, Colquitt, and Decatur) reduction in the fox population was substantial. In the

fifth county, some reduction was obtained, but the population increased subsequently.

Summary and Conclusions

In summarizing the data on fox populations applicable to the prevention of rabies, these points deserve emphasis.

Because of high birth and death rates, fox populations are essentially an annual crop. Thus, there are many new, susceptible foxes each year, and increase in numbers, even after a reduction, may be rapid.

Examination of prevalence of rabies virus in foxes or of abundance of foxes when conducted on the small scale that seems feasible is not sufficiently sensitive for predicting rabies outbreaks. Thus, the reporting of human and animal cases is still the best method of warning that preventive measures are desirable.

Trapping foxes will reduce their numbers, but the effect of such reductions on prevalence of rabies in the fox populations is yet to be determined. The agricultural trend in the southeastern United States from small farms to large tracts of timber or pasture should reduce fox numbers and consequently the amount of rabies.

proved effective in the determination of stream flow patterns. Use of radium for this purpose was first suggested by Joly in 1922 (13). In recent years, radioactive materials have been used for evaluating stream capacities for radioactive wastes. Studies on the Mohawk (14) using phosphorus-32 demonstrated the concentration of radioactive phosphorus by biota. In addition, certain hydraulic characteristics of the stream were revealed. Scandium-46 was used in tracing sewage effluent discharged into Santa Monica Bay (15). A study on the Ottawa River (Ohio) in which salt, fluorescein, and rubidium-86 were tried in flow measurements indicated that these tracer materials produced similar results (3).

Tritiated water, because of its chemical similarity to normal water, should be an ideal tracer for flow studies of this type. However, it has found limited application because of difficulties in measuring it. Tritium has been used successfully, nonetheless, in tracing flow through a model of the Savannah Tidal Estuary (16).

Ground Water

The cation exchange properties of soils are a principal deterrent in selecting effective tracers for ground-water movement. Although Fox (17) successfully employed rubidium-86, the soil studied was a porous, sandy type, atypical of most soils. Kaufman and Orlob (18) concluded that only anionic tracers, such as iodine-131, or non-ionic tracers are suitable for ground-water tracing. Chelation has been suggested as a means of converting radiocations to non-ionic form for use as ground-water tracers. The process has been demonstrated successfully in the laboratory (19).

Use of tritium as a ground-water tracer is being studied. Its concentration in ground water is also being used to determine the water's age (20).

Flow of Solids

Settling or scouring of solids from liquid media can frequently be measured directly. In some instances, however, information regarding the interchange of solids is desirable. For example, the movement of silt in the River Thames has been studied through use of sand particles tagged with scandium-46 (6).

Floc particles bearing radionuclides have been used to determine removals by filtration media. In one such study, the effective depth of penetration of floc particles in sand filters was observed by use of iodine-131 tracer (21). In another study, iron-55 and iron-59 were used to evaluate graphite, anthracite, and sand as filtration media (22).

Water Quality

Analytical procedures employing radioactive tracers have been developed for both chemical and bacteriological contaminants in water. In many instances these procedures have markedly increased the sensitivity of measurement and have simplified assay methods as well. Radioactive tracers have been used also to determine removal mechanisms and related factors in various treatment processes designed to improve water quality.

Chemical Assay

For chemical assay, two basic approaches have been explored: radiometric titration methods and neutron activation analysis.

Radiometric titration techniques using nuclide tracers to sensitize the end point have been specified for chloride and sulfate determinations. Many other applications have been suggested (23).

Activation analysis has been widely accepted in many fields for the determination of trace quantities of more than half the known elements (24). The technique is based on the fact that most elements when subjected to neutron bombardment give rise to radioactive species of the same element. The radiations emitted by these materials are characteristic of the particular element. Through study and measurement of emitted radiations, it is possible to determine the quantities of stable elements originally present in the sample.

The recent application of the neutron activation technique to the analysis of drinking water promises to broaden and extend knowledge of water quality (fig. 2). Typical elements readily determined in water by this procedure include chlorine, bromine, iodine, copper, arsenic, manganese, barium, strontium, and sodium. Concentrations in the range of 1 part in 10^9 are easily detected (25).

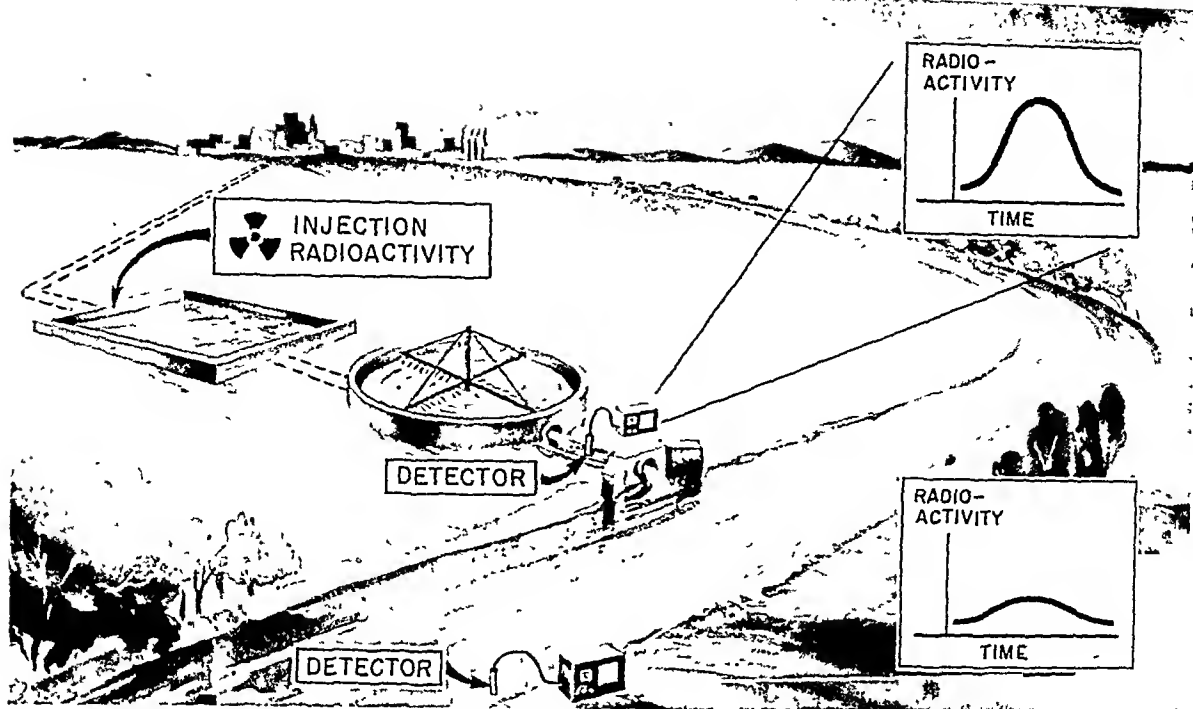

Figure 1. Hydraulics: Use of radiation in flow measurements aids study of tank design.

trolem industry. Their use enables flow measurement outside the pipe without disturbing flow conditions.

Studies on the longitudinal mixing of water in pipes, employing iodine-131, were reported as early as 1950 (1,2). The flow time within a milk pasteurization unit (short-time, high-temperature type) has also been evaluated with iodine-131 (3). Natural radon and added radium tracers have been used in studies of sewage flow (4) and outfall (5).

Leaks have been located in newly installed water mains through use of sodium-24. With this nuclide, a counting probe placed close to a pipe junction can detect leakage of as little as 100 milliliters (6). Unless the detector can be placed close to the leak, however, such methods are impractical. For example, to detect a leak 5 feet under ground would require a source strength equivalent to 3 curies of cobalt-60.

Tank Flow

Various radionuclides have been used successfully in determining detention time and dispersion in tanks. Radium was used by Hess in 1943 (7), but is no longer recommended because

of its high cost and toxicity. Today, manmade radionuclides such as sodium-24 (8) and potassium-42 (9) are being used for measurement of detention time in industrial plant systems.

For tracing sewage flow, biological compatibility of the tracer material is a principal factor. Rubidium-86 is most commonly employed, the first report of its use appearing in 1953 (10). In a comparative study of rubidium-86 and bromine-82, the flow characteristics of an anaerobic sewage treatment plant were determined (3). Similar results were obtained with these radionuclides.

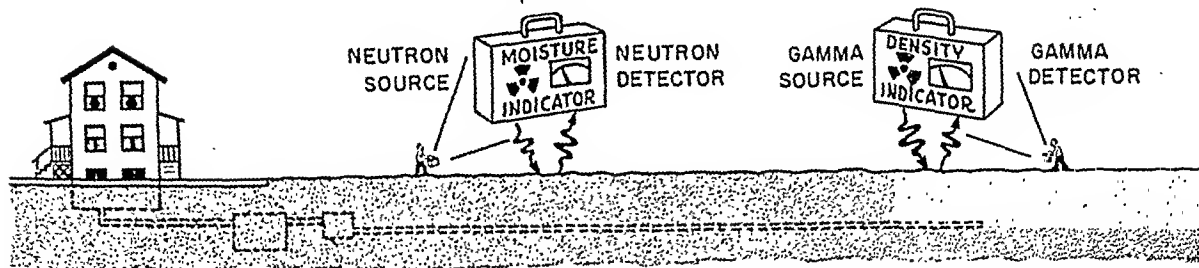

The dispersion of sewage in a 2-acre lagoon has also been determined. Here, with portable field instruments, iodine-131 tracer was measured (11).

Radionuclides are also being used in measuring silt at the bottom of large bodies of impounded water. The technique is based upon a density gauge which detects low-energy bremsstrahlung radiation (12).

Watercourse Characteristics

Many factors influence the diffusion characteristics of stream flow. Radionuclides have

Figure 4. Soil Properties: Field measurements of soil moisture and density show promise for use in designing household sewage disposal systems.

safety considerations. The neutron activation problems associated with the latter proposal might be particularly troublesome.

Studies have been made on the transport of sewage sludge through a digestion tank using raw sludge labeled with radioactive phosphorus (34). Beneficial information has resulted, particularly with regard to methods for stirring, adding, and withdrawing sludge from such systems. Use of radiation to develop new strains of biota for better oxidation of sewage has been proposed. This suggestion is based on the known ability of radiation to produce genetic changes. Through such changes improved strains of biota might result.

Other Applications

Applications of radiation in sanitary engineering cover a wide variety of other subjects.

Hydrology

Accurate predictions of runoff from snow packs are readily accomplished through use of gamma sources (35). Attenuation of the radiation by the snow itself permits accurate determinations of its depth. For example, with a 40-millicurie cobalt-60 source, depths having a water equivalent up to 55 inches can be measured and the information automatically reported from remote locations by means of a telemetering system (36).

Soil Properties

Density and moisture content of soils are amenable to measurement by use of radiation, and such measurements can be made directly in the field. In early studies, soil density was determined by the degree of gamma ray attenuation (37). In more recent developments,

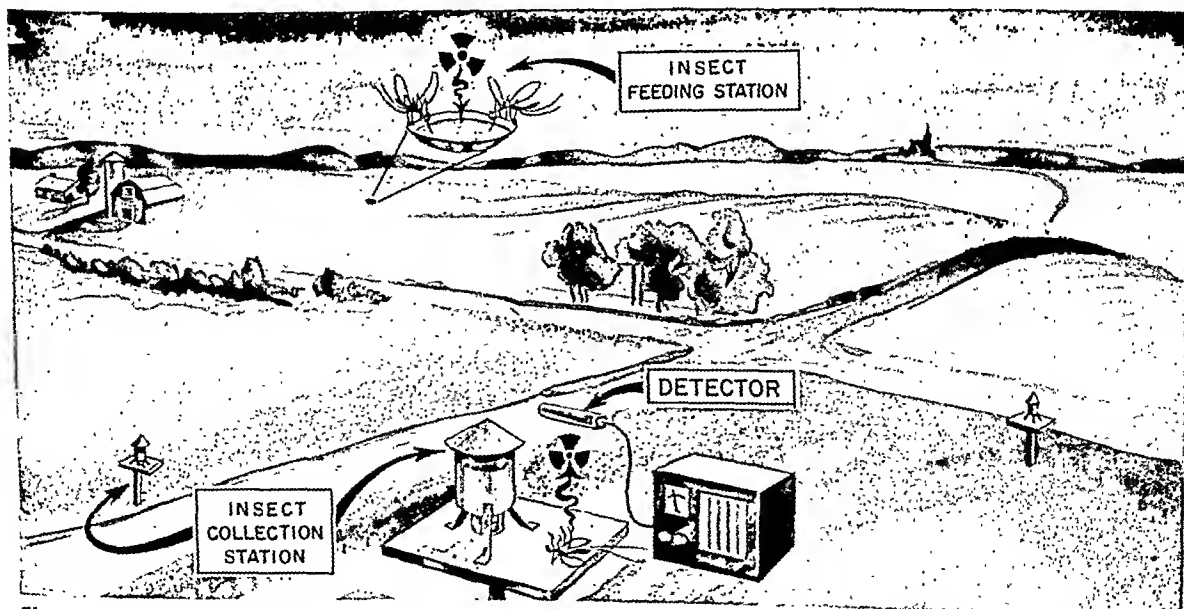

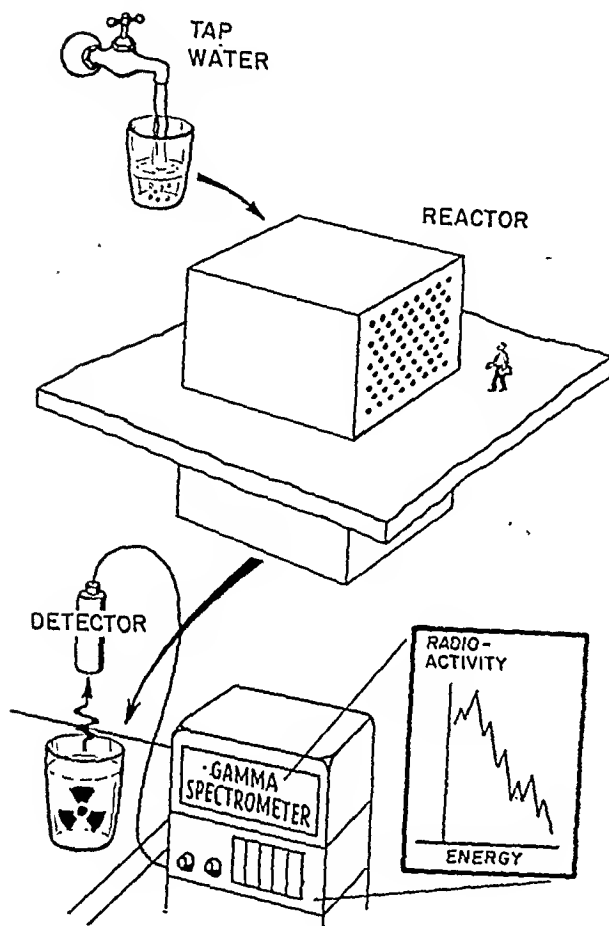

Figure 5. Insect Control: Feeding and migratory habits of insects are being studied with radiotracers.

Figure 2. Chemical Assay: Neutron activation provides an analytical method for both qualitative and quantitative determination of stable elements.

Bacteriological Assay

Basic knowledge regarding the metabolism of various food essentials by organisms has been expanded in recent years as a result of tracer techniques. A development which shows promise in the field of water quality assay is a rapid technique for the presumptive coliform test. This technique is based on the metabolism of lactose labeled with carbon-14 to form radioactive carbon dioxide (26). This metabolite, indicating a presumptive test, can be detected in as short an incubation time as 15 minutes (fig. 3).

Water and Waste Processing

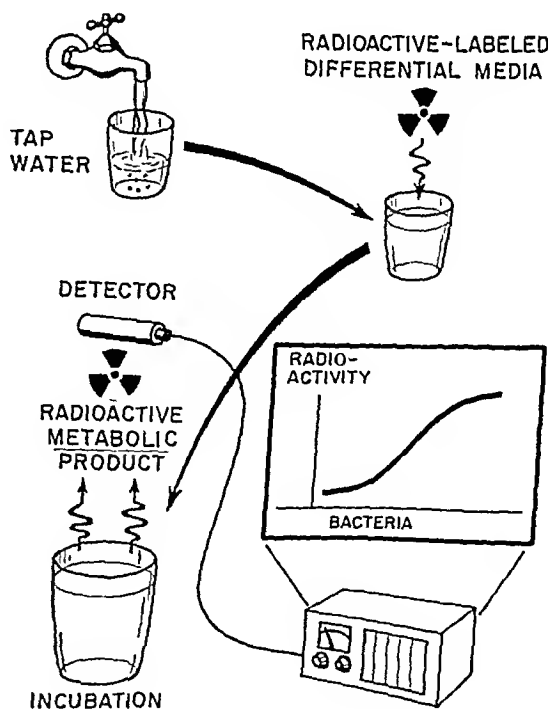

Corrosion and scale formation have concerned the sanitary engineer for many years. Today

studies employing radioactive materials promise to help him gain a better understanding of these conditions. Studies employing calcium-45 have yielded information regarding the mechanism of scale formation (27).

The mechanism by which phenol is adsorbed and desorbed from activated carbon has been investigated by using phenol labeled with carbon-14 (28). The fate of a detergent subjected to activated sludge treatment was studied by use of detergent tagged with sulfur-35 (29). With phosphorus-32 tracer, the phosphate cycle, including biota uptake and circulation, has been studied in lake water (30).

Gamma radiation for disinfection of water or sewage is frequently mentioned. Use of waste fission products in treating the material has been suggested; also sterilization of sewage by using it as a reactor coolant (31). Studies have indicated that high exposure levels (about 1 million roentgens) are required for disinfection (32,33). Hence, the feasibility of such irradiation methods is doubtful because of

Figure 3. Bacteriological Assay: Radiotracers may provide a rapid and sensitive method for the presumptive coliform test.

be endless. Hence, nuclear science is assisting substantially in attainment of the goal of sanitary engineering: the improvement of the public health, principally through the control of man's environment.

density is measured by correlation with the amount of scattering of gamma radiation when a radiation source is placed in contact with the soil (38). Moisture-content measurements are based on the neutron-moderating properties of soils. A source of fast neutrons is used in conjunction with a slow neutron detector. For most soils, the number of slow neutrons detected is proportional to the hydrogen or water content (12). These techniques offer promise in establishing design criteria for rural sewage disposal systems (fig. 4).

Insect Control

Radionuclide tracers are providing information on the travel of insects, their feeding and parasitic habits, and other factors affecting disease transmission (fig. 5). As an example, the dispersal of mosquitoes and flies has been studied using phosphorous-32 and zirconium-95 tracers (39).

For control of certain insects, particularly the screwworm fly, gamma radiation is being used to sterilize the males and thereby interrupt the reproduction cycle (12). It is envisioned that within the next few years complete eradication of the screwworm fly in southeastern United States will be possible by this means.

Another approach to insect control is the use of gamma radiation to reduce insect infestation in packaged materials. Irradiation with cobalt-60 and fission products has been studied as a technique for ridding packaged foods of various species of beetles and flies (40). Exposures of about 65,000 roentgens are required to kill, 16,000 to 32,000 to inhibit reproduction. Irradiation has certain inherent advantages over chemical fumigation, particularly the ease of application and completeness of control (40).

Food Preservation

Research indicates that all types of food can be sterilized by radiation, regardless of the species or numbers of contaminating organisms. Certain side reactions, however, may make the food less wholesome, cause changes in taste or texture, or create toxic products (41).

Transmission of trichinosis through pork products is of particular public health importance. Studies of gamma irradiation of raw pork, with cobalt-60 or fission products, have

shown that transmission of this disease can be prevented without producing detectable taste changes (42). Radiation exposure levels of about 20,000 roentgens are sufficient to inhibit the maturation of trichina larvae (43).

Food Sanitation

Cleansing abilities of detergents are being evaluated through use of radionuclide-tagged soils and bacteria. Methods for the preparation of the soils have been formulated (44). Among a variety of radionuclides tried, phosphorus-32 has proved good for tracing bacteria. Through such applications, the relationship of cleansing efficiency to type of utensil, surface conditions, and type of organism has been evaluated (45).

Air Pollution

Radionuclides have proved successful in providing data on the dispersion and dilution of air contaminants and the effectiveness of control measures. A unique method of using a radioactive gas to trace dust aerosols has been reported (46). If a radioactive gas, such as thoron, is added to a dust aerosol, the radioactive atoms of the decay products will be adsorbed by the dust particles. The resultant radioactivity of the aerosol may then be used to characterize the finest suspended matter. Dusts, so labeled, have provided information on filter efficiencies, the structure of filter media, and the mechanism of operation of sampling and control equipment.

Another application in the field of air pollution investigation is neutron activation. For example, the dispersal of nonradioactive antimony oxide from a stack was traced through irradiation of collected air samples in the reactor at the Oak Ridge National Laboratory (47). With this technique, as little as 3×10^{-9} gram of antimony per cubic foot can be detected. This is a sensitivity exceeding that of the best chemical method. It is also interesting to note that under the conditions of the experiment no radioactive material was released to the atmosphere.

Conclusion

Essentially every phase of sanitary engineering has benefited from nuclear technology, and the potentialities of the applications appear to

Effect of Natural Fluorides On Caries Incidence In Three Georgia Cities

FRED D. LEWIS, JR., D.D.S., and
ERNEST C. LEATHERWOOD, JR., D.M.D.

DENTAL HEALTH services of the Georgia Department of Public Health and of the Public Health Service in Region IV were requested by the dental society, chamber of commerce, and health department of Savannah, Ga., to make a detailed study of the prevalence of dental caries in the children of Savannah in relation to the fluoride content of its water supply. The natural fluoride content of Savannah's water supply was approximately one-half the concentration recommended by the State health department. The question was: How much additional reduction in the caries attack rate would be derived from the adjustment of this concentration to the approved range?

A dental survey was planned for Savannah and two geographically comparable communities having known concentrations of natural fluoride in their public water system. It was estimated that Savannah had from 0.3 ppm to about 0.5 ppm fluoride concentration. The Georgia cities of Macon and Moultrie were chosen as controls, for, according to the water control laboratory of the State health department, the natural fluoride content of Macon's water supply was 0.11 ppm and Moultrie's was about 0.75 ppm. These concentrations were determined from water samples collected during a 3-year period, 1954-56. (Macon obtains its water from the Ocmulgee River, Savannah, from 11 deep wells and the Savannah River, and Moultrie from 3 deep wells.) Forty samples tested for Macon showed a range of 0.0 to 0.5

ppm fluoride in the water supply. Moultrie's range was 0.3 to 1.4 ppm in 52 water samples tested.

Macon would serve as the baseline while Moultrie would indicate the caries attack rates present at the lowest fluoride level recommended by the State health department. The optimum fluoride concentration as determined by the formula relating fluid intake to mean maximum temperature (*1*) approximates the natural fluoride concentration present in the Moultrie water system. The mean maximum temperature according to the U. S. Weather Bureau station in Atlanta and Athens, Ga., was 76.6° F. for Savannah, 77.6° F. for Macon, and 80° F. for Moultrie, over a period of 82, 57, and 24 years respectively.

Over the years, Savannah has continually expanded, outreaching and overtaking the public water system. To meet the increased demands, new wells were added directly to the water system at the point of greatest need. Today there are 11 independent deep wells and a surface supply with 2 separate pumps. Between March and October 1956, 138 samples from all water sources showed a range in fluoride of 0.0 to 0.8 ppm. The average fluoride concentration for each well ranged from approximately 0.31 ppm to 0.53 ppm, while the surface supply averaged about 0.06 ppm. This resulted in an overall numerical average of about 0.37 ppm fluoride concentration (table 1). Since records have been kept only in recent years on the fluoride concentration in the water system, the assumption was that the samples taken in 1956 would be indicative of the fluoride concentration in the water system for the entire life of the children examined.

The pumpage rate of each well fluctuated, depending upon the needs of the system, and since there was no common reservoir, there was no distribution constant. During 1956, the pumpage rate of individual wells varied from approximately 28 million to 1.4 billion gallons of water, and the surface source supplied about 35 million gallons. The inconstant pumpage rate and variation in the fluoride concentration necessitated the determination of a weighted average fluoride concentration in the water system for the year. By dividing the total

Coordinator of International Affairs

A new position, Departmental Coordinator of International Affairs, has been established in the Department of Health, Education, and Welfare.

The new position will coordinate international activities related to health, education, vocational rehabilitation, social insurance, social welfare, and other areas within the Department and provide liaison with other Government departments and agencies having international concerns. The Department's operating agencies will continue to hold direct administrative responsibility for the international aspects of their programs.

Robert A. Kevan has been named to fill the new post. He served as special assistant to the chief medical director of the Veterans Administration and for 2 years was assistant chief of the Formosa field office of a management consultant firm before coming to the Department in March 1958 as assistant to the Assistant Secretary.

reason for extractions: orthodontic purposes, trauma, or otherwise.

3. Number of primary and permanent teeth needing extraction.

4. Number of unfilled carious teeth and number of surfaces involved.

5. Number of filled teeth and number of surfaces restored.

Findings

A total of 9,301 school children participated in this dental survey, 3,890 from Macon, 4,871 from Savannah, and 540 from Moultrie. Even though the number of children in Moultrie was relatively small, when the data from all three communities on caries-free children and on decayed, missing, and filled (DMF) teeth were subjected to the chi-square test, they were found to be statistically significant (4).

Table 2 shows the number of children examined as well as the percentage with caries-free permanent teeth. The total for all ages shows that for permanent teeth, 17.1 percent of the children in Macon are caries-free, while 23.3 percent of Savannah's children are caries-free, and 44.3 percent of Moultrie's children are caries-free.

The percentage difference in the total DMF rates, as shown in the last three columns of

Decayed, missing, or filled permanent teeth per child by age, Macon, Savannah, and Moultrie, Ga., 1956-57.

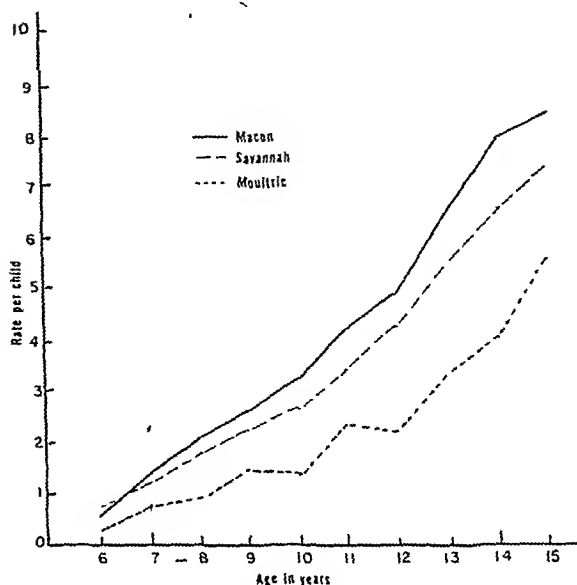

table 3, indicates that the children of Savannah have 35.6 percent fewer caries than those of Macon. Moultrie shows 60.8 percent less dental decay than Macon and 39.1 percent less than Savannah.

The difference in the decayed, missing, or filled rate per child at each age in the three cities is shown in the chart.

parts fluoride from each well by the total number of gallons pumped, a concentration of 0.38 ppm was calculated.

Materials and Methods

A survey technique to obtain the required data was decided upon early in the planning stage (2). Participation in the dental survey was limited to white school children 6-15 years of age who were continuous residents, had used only the public water supply since birth, and had parental consent.

Careful dental examinations were conducted by two dentists, Hubert H. Martin from the

Georgia Department of Public Health and Ernest C. Leatherwood from Region IV, Public Health Service. A tooth surface was considered carious if the end of the dental explorer penetrated the soft, yielding tooth structure; if, in the case of pits and fissures, the explorer caught, supported its own weight, and met resistance when it was withdrawn; or if the surface had a carious lesion which was clinically obvious. The observations of the two examining dentists were recorded in code on the patient's chart (3) along with the following data:

1. Number of teeth erupted.
2. Number of permanent teeth extracted and

Total-----	2,327	3,381	380	8,581	10,532	1,069	3.69	3.11	2.81

An analysis of the decayed-filled (df) rate in primary teeth is presented for these cities in table 4. Moultrie has the lowest df rate for the children examined.

Discussion

From the findings, it is obvious that an inverse relationship exists between the caries attack rates and the concentration of fluorides in the water system of these three communities. Approximately one-fourth of the permanent teeth of the children examined in Macon were decayed, missing, or filled, one-fifth in Savannah, and one-ninth in Moultrie.

The DMF rates of the 12-14-year-old groups in Macon, Savannah, and Moultrie can be plotted upon Deau's graph of dental caries experience in 21 cities (5). The pattern is similar even though these rates occur in cities with a warm climate.

The DMF percentage difference between Savannah and Moultrie demonstrates decisively the additional protection against dental decay that could be achieved in Savannah by increasing the fluoride concentration of the water system from 0.38 ppm to at least 0.75 ppm (but no more than 1.0 ppm).

Conclusion

Savannah, with a natural fluoride content of about 0.38 ppm in the water system, is providing its children with 35.6 percent protection against dental decay. An additional 39.1 percent reduction in caries would be expected if

Savannah were to increase the fluoride concentration to equal Moultrie's (0.75 ppm). Macon, with only a trace of fluoride in its water system, would expect to reduce dental caries in its children by at least 60.8 percent with adequate fluoridation.

Summary

A dental survey of 9,301 continuously resident, white school children between the ages of 6 and 15 years was conducted in the cities of Macon, Savannah, and Moultrie, Ga., in order to determine the effect of different concentrations of natural fluoride in the water systems upon the rate of dental decay.

The natural fluoride concentration was approximately 0.11 ppm for Macon, 0.38 ppm for Savannah, and 0.75 ppm for Moultrie. The mean maximum annual temperature for these cities was 77.6° F., 76.6° F., and 80.0° F. respectively.

On a percentage basis, Moultrie had about twice as many caries-free children as Savannah and more than two and one-half times as many as Macon.

The decayed, missing, or filled (DMF) rate for permanent teeth per child was 4.64 in Macon, 2.99 in Savannah, and 1.82 in Moultrie.

Moultrie's DMF rate was 60.8 percent lower than Macon's and 39.1 percent lower than Savannah's; Savannah's was 35.6 percent lower than Macon's.

The decayed-filled rates for primary teeth were slightly lower in Moultrie than in the other two communities.

Epidemiological Note

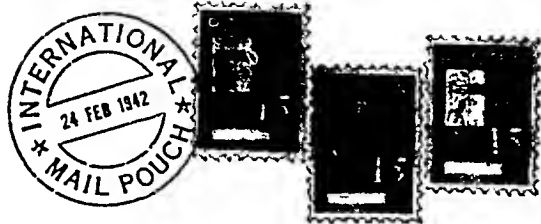

Smallpox

The recent occurrence of smallpox in Germany, which was introduced by a traveler from India, prompted the application of rigid requirements for vaccination of persons entering the United States from Western Europe. There was need for making the requirement apply to persons traveling from more areas than the one where the index case eventually was hospitalized. He had symptoms of the disease while traveling by plane from the Far East, and fellow travelers destined for various parts of Europe were exposed to infection. He also stopped in Switzerland before going to Germany. Secondary cases and one death have been reported, all of them from the area of Germany where the index case was found.

Failure to recognize the possibility of smallpox in persons traveling from infected areas has been followed by several localized outbreaks in Europe in the past

decade. In each instance, it has been necessary to apply rigid vaccination requirements for travelers from these epidemic areas before entrance into the United States.

The United States has not been immune to the introduction of the infection from other countries. In one instance in 1946, a soldier returning from Japan developed smallpox en route to Seattle. In spite of isolation, the disease spread, and there was a final total of 28 cases with 8 deaths. In 1947 a man traveling from Mexico City by bus presumably developed first symptoms of the infection en route to New York City. This case was not recognized as smallpox except in retrospect. In this outbreak, there were 9 cases with 2 deaths including the first case. These two outbreaks show very clearly what may happen if the infection is introduced and why rigid requirements for vaccination of persons subject to possible exposure are justified. Vaccination is required for protection not only of the traveler but also of the public.—DR. CARL C. DAUER, medical adviser, National Office of Vital Statistics, Public Health Service.

Water Hunter

Experience in ground water exploration sometimes pays off. After 2 months of exploratory work, contract technicians reported that no water was available for a certain small town in Brazil. An experienced engineer and a crew from Serviço Especial Saúde Pública located a 4-meter stratum of good, water-bearing sand 10 hours after they arrived in the area.

—E. ROSS JENNEY, M.D., *chief, Health and Sanitation Division, U. S. Operations Mission, Brazil.*

26 Million Tails

With all the returns counted in its nationwide campaign, the Ministry of Health and Social Welfare of the Republic of Korea has collected 26,994,758 rat tails. The 2-month eradication effort was to combat foci of typhoid fever. However, a second wave of the disease hit Pusan, where 97 cases including 8 deaths were reported, 3 months after the campaign ended.

—ALFRED S. LAZARUS, Ph.D., *chief public health adviser, U. S. Operations Mission, Korea.*

Teamwork

International teamwork helped Thailand combat a cholera epidemic in May and June 1958. Following news of the outbreak, 500,000 cc. of vaccine from the Serum and Vaccine Laboratories of the Philippines Government and an equal amount from reserve supplies in the United States were flown to Thailand. UNICEF sent equipment to produce the vaccine, and a United States Navy medical research team from Taiwan went to Bangkok to give bacteriological and epidemiological assistance.

The first cases were reported in Bangkok May 23, and the outbreak reached a peak 15 days later when 230 cases were reported. Twenty provinces reported cholera, and by the end of June, Thailand had nearly 6,000 cases with 868 deaths. The fatality rate, at first over 15 percent, dropped below 10 percent as

treatment facilities improved and intensive vaccination and health information campaigns gained momentum.

After a few cases occurred in neighboring Cambodia, mass inoculation began and preventive measures were publicized. Part of the vaccine used in Cambodia was produced at the Pasteur Institute in Phnom Penh, using equipment provided several years ago by the Agriculture Division of the U. S. Overseas Mission.

Droit du Seigneur

In 1954, during one of my visits to the village training institute at Rahimyar Khan, West Pakistan, I showed a motion picture on constructing an earth privy. About 2 weeks later when I returned, I was met at the train by the institute's principal, several instructors, and many of the trainees. Their salaams were hasty and they seemed excited as they escorted me to a jeep and whisked me off to the institute, instead of to the resthouse, the usual first stop to unpack, bathe, and breakfast.

At the institute, as the trainees lined up, did a military right face and marched forward, the principal indicated I was to follow. The line of march halted 75 yards away in a corner of the campus. There, guided by the motion picture, the trainees had constructed an earth privy, complete with superstructure, the first ever built at the institute, and probably the first in the state of Bahawalpur.

A red ribbon was strung across the entrance, and the trainees indicated that I, their "uncle," a term young Pakistanis use to show respect to an older man, was to officiate at the opening. The students cheered and camera shutters clicked while I cut the ribbon. I repeated the act so that all the photographers could get their pictures.

I complimented the trainees and turned to go, but excited voices told me my ceremonial duties were not ended. Their American "uncle" was also to be the structure's first guest.

Disposal of Industrial Wastes by Irrigation

F. H. SCHRAUFNAGEL

RESPONSIBLE officials are interested in a waste disposal or treatment facility that is economical to build and operate, requires little attention, and still does a satisfactory job. Disposal by irrigation meets these specifications for some industrial wastes, and it has attracted a great deal of interest recently. Irrigation as a means of disposal is not new; this method was used extensively on sewage farms beginning in the 1860's and 1870's.

The two principal methods of using irrigation to dispose of waste water on the land are ridge and furrow irrigation and spray irrigation. In the ridge and furrow method, wastes are disposed of in furrowed plots. Early systems used a single or a few furrows, and the wastes were directed manually to another furrow when one was full, a technique that can also be used with contour furrows on sloping land. On relatively flat land, two or more plots are usually developed.

Wastes are discharged to a main or header ditch, which may be in the center of the plot or at the side, and then flow into the furrows which are nearly level but at a higher elevation. Furrows are 3 to 15 feet apart, 1 to 3 feet deep, and 1 to 3 feet wide. When wastes in one section build up to about 6 inches from the ridge tops, a control gate can be set for overflow into

another area. Control gates can also be used to take an area out of service for maintenance or to rest the land.

Compared with spray irrigation, ridge and furrow systems have a higher original cost and a lower operating cost, and can handle higher volumetric loadings. They have no problems caused by freezing during cold weather. But they are more likely to develop into a nuisance and may require additional land to get farther away from factories, dwellings, or public roads. Because land irrigated in this manner is difficult to crop, grasses are frequently left uncut, but noxious weeds must be destroyed.

Disposal by spray irrigation is a recent development in this country. The first installation of this type appears to have started operating in 1947. Only a few had been installed prior to 1950, but since that time use of this method has mushroomed. Wastes are sprayed onto the land, usually through revolving nozzles. Lightweight metal or plastic pipe is frequently used to convey wastes from a wet well or holding pit to the disposal field. Pipe sections can be moved easily to change spray areas, and, in some cases, extra piping and a valving arrangement can divert wastes to different locations.

The land does not require special preparation and moderate slopes can be tolerated. Woodland, brush areas, pastures, and cropland have been used successfully for waste disposal. Generally, it has been easier to obtain land for spray irrigation than for ridge and furrow systems. In a few cases, industry has been given use of land in exchange for the wastes and their possible fertilizer and moisture

Mr. Schraufnagel is associate public health engineer for the Wisconsin State Committee on Water Pollution at Madison. The article is based on a paper presented at the ninth annual meeting of the Middle States Public Health Association, April 28, 1958, Milwaukee, Wis.

value. Spray-irrigated grasslands are sometimes cropped. The biggest disadvantage of spray irrigation is the difficulty of operation during freezing weather. Some factories which dispose of wastes daily use spray irrigation during warm weather and ridge and furrow or other methods in the colder months.

Dairy Wastes

Dairies, many of them in rural areas and small villages close to the milk supply, are the source of the industrial waste most prevalent in Wisconsin. In June 1956, the State had a total of 1,625 factories engaged in the processing of milk and allied products from a yearly farm production of 16 billion pounds.

These factories create a variety of wastes, depending on the type of operations, the inclusion of concentrated wastes, and whether or not all or part of their cooling water is used in irrigation. The wastes may have a biochemical oxygen demand (BOD) ranging from less than 200 ppm for receiving station wastes to 15,000 ppm for a cheese factory discharging excess whey along with wash water wastes.

In 1954 the Mindoro Cooperative Creamery in western Wisconsin began operation of a ridge and furrow system with pumping facilities. Its irrigation area of about 3 acres is divided into 3 plots which are underlaid with 2 lines of drain tile. Cost of the completed system, including \$2,000 for land and \$2,000 for pumping facilities, was approximately \$8,000. This system accomplished a high degree of treatment; the BOD increase in the receiving stream is only 0.1 ppm, compared with 41.6 and 26.0 ppm before ridge and furrow facilities were installed.

About 20 other Wisconsin milk plants, mainly creameries, now have ridge and furrow systems. Minimum rates of waste disposal vary from less than 3,000 to more than 32,000 gallons per acre per day (gpac). Original costs ranged from \$300, for a small factory where 3 furrows were dug and gravity flow was used, to approximately \$25,000, for a large plant where the disposal field required extensive leveling.

A nuisance is more likely to develop in warm weather when a ridge and furrow system

is used for wastes with high BOD concentration; therefore, cheese factories have been encouraged to adopt spray irrigation. Occasional excess whey apparently can be handled without difficulty, but operators are cautioned about overloading systems with whey. Milk wastes have little gross solids in them, and elaborate screening is not required. The systems usually need a small basket screen or bucket with holes under the holding tank influent line to collect bits of curd, steel wool, brush bristles, and matchsticks, thus keeping them out of the nozzles. Scum and sludge will develop and accumulate in the holding tank, but this can be prevented by tapping off a $\frac{3}{8}$ -inch or $\frac{1}{2}$ -inch line beyond the pump, and returning some flow to the tank to agitate its contents.

Wisconsin now has about 30 milk plants using spray irrigation. Original cost, excluding land, ranged from \$300, for a small factory whose operators used old equipment and did most of the construction work, to \$5,000. Some disposal rates average only 2,000 gpac in extremely heavy soils while in favorable soils, rates of 10,000 to 15,000 gpac are sometimes achieved.

Six plants, mostly cheese factories in southern Wisconsin, continue spray irrigation during the winter. To prevent freezing in their systems these plants use a holding tank large enough to store 1 day's waste, a well-insulated pump and motor, and a heat lamp. The pump is started around noon, generally the warmest time of the day, and runs continuously for about 2 hours until the end of the work day. Pipes are supported on posts and slope back to the wet well. An icecap up to 2 feet thick may develop around the sprays. Most of the vegetation under the ice is permanently killed off, and these spots must be reseeded in the spring.

Waste temperatures of 90° to 100° F., an advantage for winter spraying, have been found at some of the cheese plants. A whey processing plant whose wastes at 135° F. killed vegetation solved this difficulty by extending the discharge to 10 feet above the ground and using a finer spray nozzle. Whey condensate at one plant caused corrosion of the aluminum pipe, which was replaced with copper tubing.

Ridge and furrow irrigation system serving a milk plant. Furrows lead away from the main, or header, ditch in the foreground.

Spray irrigation during the warmer months has vastly improved conditions around some milk plants where wastes previously were a nuisance. One operator felt the change was worth \$1,500 to him. In small communities near a resort area or a summer military camp where a milk plant contributes a significant part of the normal municipal waste, it may be easier and cheaper to irrigate the milk wastes than to enlarge sewerage facilities for the larger summer population.

Vegetable Processing Wastes

A 1913 report by the Water Survey of Illinois, mentioned in a 1939 bulletin, *Methods of Treating Cannery Wastes* (1), indicates that irrigation of pea and corn wastes in a large field gave best results. At the 1947 Purdue Industrial Waste Conference, Bolton (2) dis-

cussed Iowa canning plants which had started using ridge and furrow disposal 13 years earlier. In 1934 Iowa had 10 such installations for

The milk plant's system, photographed from the same point, after grass became established.

disposal of cannery wastes. He described the operations at the Hampton and Waverly plants in detail, since they had been functioning for several years. The Hampton cannery had a BOD loading of about one-ninth that of Waverly's, or 230 pounds of BOD per acre per day compared with 2,030 pounds of BOD per acre per day, although volumetric loadings for both averaged about 50,000 gpad.

Monson (2) reported that the Green Giant factory at Watertown, Minn., disposed of an average of 4.3 inches per day, or 116,000 gpad, on a ridge and furrow field. Generally, application rates for such systems range from about 5,000 to more than 100,000 gpad.

Canning operations are usually conducted during the summer when infiltration and evapotranspiration are highest. To my knowledge, no canneries in Wisconsin have used ridge and furrow irrigation exclusively for waste water disposal. However, in 1954 the California Packing Co. at Arlington used ridge and furrow for temporary disposal of wastes when its lagoon became full, and several pea viner stations have handled their stack juices by this method.

Spray irrigation of wastes from canning plants has become popular. There were no such installations in Wisconsin until 1951, when 11 were installed; by 1955, there were 40, representing 30 percent of the State's canning plants. The results, on the whole, have been gratifying, and many chronic pollution situations have been eliminated. The factories are requested to provide duplicate or standby pumping facilities, have thorough screening, and operate the system without ponding or rimoff. When these conditions are met at an approved site, there is little danger of pollution or a nuisance.

Poultry and Tannery Wastes

A poultry processing establishment of Vallo-Will Farms, Inc., near Lake Geneva, Wis., treated its wastes, approximately 120,000 gpd with 220 pounds of BOD, in a high-rate trickling filter which accomplished an 80 percent BOD removal. This treatment was inadequate for the small receiving stream, and complaints were frequent. The effluent was chlorinated in

1954, and spray irrigation was started during the nonfreezing months. These measures eliminated discharge to the stream and also most of the complaints.

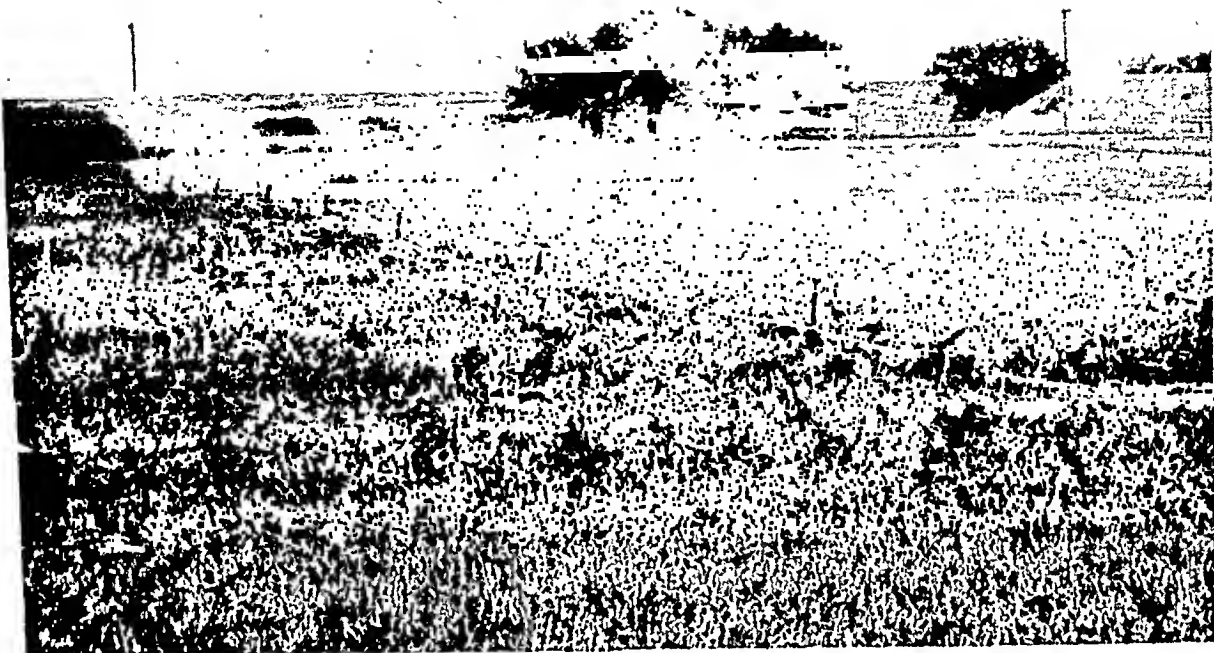

A ridge and furrow system was installed in the summer of 1957 when Edward Alf and Son of Endeavor, Wis., began operating a chicken processing plant. Two adjoining plots with a combined area of 1.05 acres and underdrained by two lines of 6-inch drain tiles were used. A "sparkling" effluent was noticed upon occasional observation, although wastes in the ditches and furrows are quite red. As yet, a detailed survey of the system has not been conducted. However, the waste volume amounts to an estimated 60,000 gpd on the 4 days a week the plant operates. A single grab sample from the drain tile in November 1957 had a BOD of 5.5 ppm. Solids, particularly feathers, are beginning to accumulate and improved screening is needed. An additional area of sandy soil is available for expansion.

A tanning plant which uses vegetable dyes in Pennsylvania spray irrigates wastes during critical stream periods from mid-May to late November (4). Wastes amount to 425,000 gpd and have a BOD of 2,300 ppm associated with a total solids concentration of 10,550 ppm. A 1,200-gpm pump, powered by a 150-hp diesel engine, applies the screened raw wastes to the land over a 6- to 7-hour period. Fifteen acres of land, whose soil consists of about 4 feet of sand over gravel, is used for disposal. Grasses were killed off originally, but in areas which are not sprayed for a time, vegetation grows profusely. A sludge layer accumulates and the plot is disk-harrowed every 3 weeks. Apparently no odor has been associated with spray irrigation of these wastes.

Pulp Wastes

Several Wisconsin pulping mills have experimented with and used irrigation to dispose of spent sulfite liquor. Approximately a ton of solids is dissolved from the wood for each ton of pulp produced. A 100-ton mill produces 200,000 gallons per day of this liquor, which has a BOD of 28,000 to 40,000 mg. per liter.

Studies of soil filtration were conducted by

Spray irrigation system in operation. Revolving nozzles are in a line perpendicular to the main line which crosses the foreground.

the Sulphite Pulp Manufacturers' Research League and reported by Wisniewski and associates (5). Ten-foot columns of mixtures of various media were used for experimental purposes, and different filtration rates were applied. Generally, BOD removal varied with the loading rates from a high of 95 percent, when 0.18 pound of solids was applied daily per square yard, to a low of 10 percent, with 12.3 pounds of solids. A field trial was made at a spray irrigation system, and removals of 40 percent were experienced with mean temperatures above freezing. During very cold weather the removal dropped almost to zero. In warm spring weather the BOD removal returned to about 30 percent.

In their report, the authors suggested consideration of the following principles of design and operation: (a) the effectiveness of microbiological reactions of the soil is greatly

reduced if loadings of unstabilized organic matter exceed the rate of complete reaction; (b) the amount of water fed to the soil must be so controlled as to avoid sustained periods of flooding and the anaerobic conditions which result from flooding; and (c) geologic conditions must be such as to avoid the possibility of contamination of ground water supplies.

The Flambeau Paper Co. at Park Falls began using the irrigation method of disposal for some of its wastes in 1954. During critical stream conditions spent sulfite liquor is hauled out to a 40-acre disposal area by truck. The trucks dump along the road, constructed on a ridge in the area, which is wooded and has rock outcroppings. A bulldozer is used to construct absorption ditches. An aerial survey showed that about 40 percent of the trees were killed.

This pulp mill also spray irrigates some of its wastes on a 2-acre island which has a bark and

sawdust fill. The system has been able to apply the wastes satisfactorily through the winter but with a marked reduction in effectiveness.

The Kimberly-Clark mill at Niagara disposes of up to 250,000 gpd of spent sulfite liquor to a plot of sandy soil over rock. A pump, mounted on a trailer, is towed behind a truck and fogs the wastes out to a distance of 40 feet along each side of the road at a rate of less than three-fourths of a pound of solids per square yard. Four miles of road have been constructed to carry out the disposal of wastes in this manner.

Irrigation treatment of pulping wastes is poor compared with the treatment of wastes from food processing industries, and there is also danger of the sulfite liquor concentrating in underground pockets and polluting ground water supplies for extended periods. For these reasons irrigation of pulp wastes is considered only a temporary means of disposal.

Meat Packing Wastes

Oscar Mayer and Co., Madison, Wis., began experimenting with irrigation disposal of wastes in 1951 and started field disposal in 1953. Wastes are pretreated to remove grit, panicle manure, and grease, then subjected to flocculation and sedimentation. Secondary treatment, accomplished through trickling filters and sedimentation, is provided before discharge either to the Madison Metropolitan Sewerage District or to the irrigation fields.

The plant has 200 acres of land available for irrigation. In 1954, 17 percent of its wastes were disposed of by irrigation, with an application rate during the irrigation period of 10,000 gpad. The largest daily waste quantity that has been irrigated is 2,900,000 gallons. Quantities may vary considerably from day to day depending on such factors as rainfall and cropping. Wastes were spray irrigated until 2 years ago when the practice was discontinued because of complaints about odor by residents of an area near the disposal field. But it was not shown that the complaints were justified. Since that time, disposal on land has been mostly by flood irrigation. Mosquitoes caused the most trouble in 1957, and the best method of control was to dry out the various disposal areas at least every 6 days. Diking and careful operation are required so that wastes do not overflow.

Because wastes containing nutrients for algae must be kept out of the Madison lakes, irrigation is carried on only during the growing season, from mid-April to early November, when vegetation utilizes the fertilizer constituents of the wastes. The high sodium concentration of the wastes, about three times the maximum acceptable for irrigation, may eventually cause a soil problem if this concentration is not reduced.

The purposes of the plant's system are to reduce the sewer service charges and to demonstrate the use of a waste effluent for land irrigation. Because the campus of the University of Wisconsin in Madison is nearby, the project has received close study from its inception, and information about it has been published (7). Undoubtedly further findings will also be made available.

Evapotranspiration

What happens to an irrigated waste? Part is evaporated, some may be transpired, and the remainder is filtered away into the ground. A relatively small amount of mineral matter is used by the vegetation, but only water is transpired and evaporated so that the soil solution will contain higher quantities of solids than were present in the original waste water. The rate of evaporation of the liquid depends on temperature, humidity, and the area exposed, while the rate of transpiration depends mainly on leaf area, humidity at plant level, amount of solar energy, and available moisture. Under field conditions it is difficult to consider separately the water consumed by evaporation and that by transpiration, and the two are frequently lumped together as evapotranspiration, or consumptive use. The maximum consumptive rate for water is about 0.3 inch per day, or slightly more than 8,000 gpad during the hot, dry months. This rate is affected little by the type of forage crop. Normal evapotranspiration is 3,500 to 7,000 gpad.

Vegetation, by transmitting water and keeping the soil loose, is important to the success of a disposal system. Reed canary is probably by far the grass best suited for ridge and furrow irrigation plots in Wisconsin. It is a permanent grass and a heavy producer, has a substantial root structure, and endures water and ice sheet coverage very well. A seeding rate of

8 to 10 pounds per acre with the seed not covered too deeply is recommended. Brome grass and Kentucky bluegrass are probably next best suited, but they do not endure water and ice coverage as well. Some systems have developed good growths by seeding a mixture of these grasses. Trees and brush also do a good job of water transmission at some locations.

Pulp and tannery wastes from some plants have killed the vegetation originally present. The pH, temperature, or waste constituents may not have been suitable. Also, aeration in the root zone is considered essential for most vegetation. Hydrogen sulfide and nitrites are toxic to plant roots, and these compounds can be formed by waste decomposition when sufficient oxygen is not available. Occasional flooding can be tolerated, and flooding can be more frequent when plant life is dormant.

Opinions and findings as to what constitutes a suitable irrigation water vary greatly. Soil, drainage, crops, and climate are among the determining factors. Sandy and gravelly soils that are well drained can tolerate much higher concentrations than clay and poorly drained soils. Irrigation water is considered for total salts and the ionic concentration as shown by the water's specific conductivity; quantity of sodium and its ratio to other cations; amount of bicarbonate; and concentrations of boron, chloride, and sulfate.

Infiltration

Excluding the runoff, excess moisture can only percolate or infiltrate the soil at some periods. Evaporation and transpiration cease at times, and precipitation, in addition to waste waters, must also be handled.

According to Musgrave (6) the major factors that affect the intake of water by soil are surface condition and amount of protection against the impact of rain; internal characteristics of the soil mass, including pore size, depth, or thickness of the permeable portion, degree of swelling of clay and colloids, content of organic matter, and degree of aggregation; moisture content and degree of saturation; duration of rainfall or application of water; and season of the year and temperature of soil and water.

Musgrave also stated that, in the same soil, intake rates were higher when irrigation was

applied by flooding than they were from artificial rainfall; infiltration rates increased progressively from bare ground to row and cover crops; infiltration rates increased progressively for more than 20 years after a soil was taken out of cultivation; seepage was better when the soil was protected by mulch, burlap, or grass from surface compaction by raindrops; rates were better when wheat stubble was left than when the area had been burned off; and infiltration rates increased with temperature.

In a 72-hour continuing test with varying water and soil temperatures, the infiltration rate varied diurnally with the temperature from 0.18 inch per hour at 35° F. to 0.54 inch per hour at 70° F. Nearly an exact correlation was found between infiltration and viscosity. Musgrave also included a tabulation of more than 100 soil types tentatively arranged according to their minimum infiltration rates.

Treatment and Drainage

Waste is purified by micro-organisms as it filters through the soil. General principles of filtration indicate that progressively higher BOD reductions, within limitations, are achieved by finer filtering materials, lower rates, and warmer temperatures. Although much progress has been made in sewage treatment, we still have nothing that can produce a better effluent than the intermittent sand filter. The theory of sand filter operation indicates that the best results are achieved by giving the filtering media a chance for aeration.

Vegetation and drain tile should help maintain aeration of the soil, but intermittent operation may be advisable at times. A nearly complete removal of suspended solids and a large reduction in bacteria will be achieved by percolation through the soil pores. In addition to the treatment the wastes receive, irrigation usually acts as an effective flow equalization unit in distributing percolate flow and strength over 24 hours rather than the 6 to 8 hours per day that small factories operate, and stream improvement is greater than the degree of treatment indicates.

If a system is operating satisfactorily and has been properly located, there should be little danger of contaminating wells unless the disposal field is in an area with creviced limestone

near the surface of the ground or unless the waste contains sulfite liquor. This type of waste is acidic and concentrated, responds slowly to biological treatment, and can cause pollution over a long distance and time.

Some soils are naturally well drained, and, in others, drain tile can frequently be used to advantage. Drainage not only permits higher volumetric loadings but removes concentrated salt solutions and, through soil re-aeration favors the treatment processes involved in waste stabilization.

Care must be exercised in using drain tile. Difficulty from earlier drain tiling occurred at some dairy and cannery spray irrigation fields. Short circuiting due to shallow depth or broken tile and the effects of strong wastes must be watched. A minimum tile depth is $2\frac{1}{2}$ feet: vegetation growths increase with drain tile to depths of 3 or 4 feet. The water table between the tile lines will be arced, but even on tight soils it is doubtful if a distance of less than 20 feet between lines is warranted.

An open ditch or a nearby stream with a water level several feet lower than the furrows helps drainage. An irrigation system might be laid out parallel to the bank or on the inside loop of a meandering stream to insure good drainage.

Conclusions

In general, waste irrigation has accomplished a good degree of treatment at low cost. Adverse effects have occurred in only a few cases.

Waste irrigation is not a cure-all but rather should be considered as another method of treatment that can be used when conditions are suitable.

Epidemiology Course for Nurses

A refresher course in communicable disease control stressing epidemiological principles and techniques will be held April 20 through May 8, 1959, at the Communicable Disease Center, Atlanta, Ga., for public health, industrial, and other nurses having supervisory, teaching, or consultant duties.

Courses include epidemiological principles, the laboratory and statistical methods in field epidemiology, and nursing care in communicable disease, for which field practice can be arranged.

There is no fee for the course. Applications should reach the Center by April 1, 1959. They may be obtained from the Chief, Nursing Section, Epidemiology Branch, Communicable Disease Center, Public Health Service, 50 Seventh Street, NE., Atlanta, Ga., or from State health departments.

The Epidemiology of Leptospirosis in the United States

MILDRED M. GALTON, Sc.M.

DURING the past 70 years extensive investigations have shown that leptospirosis occurs in humans and animals in all parts of the world and that it is not a single disease but a group of diseases caused by a variety of leptospiral serotypes. Although considerable attention has been directed to the study of leptospiral infections by European and Asian workers since the early 1930's, much of our knowledge regarding the epidemiology, public health importance, and distribution of these diseases in the United States has been gained only during the past decade.

The epidemiology of the leptospiroses has been shown to follow a characteristic pattern based, in part, upon the fact that they are zoonoses, diseases transmitted from animal to animal and from animal to human. The chain of transmission, with rare exception, stops with human infection.

For many years rats and dogs were considered to be the primary animal carriers, but as the search for leptospires continues the host range broadens not only among domestic animals but in a variety of feral mammals (1). Leptospirosis now constitutes a major problem in cattle and swine, and in some areas sheep, goats, and horses become infected. The rat is one of many rodent carriers including mice,

voles, and shrews (2-4). In addition, bats, mongooses, bandicoots (5), jackals (6), foxes, opossums, raccoons, skunks, and wildcats (1) have been found infected. In these host animals, leptospires become localized in the kidneys and may be found in the lumina of the convoluted tubules. They may be shed in the urine for long periods.

Each leptospiral serotype usually is thought to have a primary animal host but it may infect other animals, and a so-called primary host for one serotype may become infected with other serotypes or even harbor two types at the same time (7). A classic example of this is *Leptospira canicola*, found principally in dogs; it has also been isolated from cattle (6), swine (8), and jackals (6), and serologic evidence suggests it may infect raccoons (9). Dogs have been found to harbor at least nine other serotypes (10).

Differentiation of the rapidly increasing number of pathogenic leptospiral strains is highly important from an epidemiological and epizootiological point of view. This became apparent to the Dutch workers in the early 1930's who found that classification of leptospires must be based upon serologic analysis. During the next 20 years these investigators studied antigenically distinct strains isolated in various parts of the world and developed techniques for serologic identification. Finally, in 1954, Wolff and Broom (11) published a suggested classification scheme based on antigenic analysis which included 34 leptospiral serotypes isolated from man and animals. In the 3 years since this report, approximately 25

Mrs. Galton is chief, *Leptospira* Research Laboratory, Communicable Disease Center, Public Health Service, Chamblee, Ga. This paper was presented at the CDC Conference for Teachers of Veterinary Public Health and Preventive Medicine, and Public Health Workers, Atlanta, Ga., June 12-18, 1958.

additional serotypes have been described in Australia (12,13), Africa (14), Europe (15), and Malaya and the United States (16).

Serotypes in the United States

The primary *Leptospira* serotypes in the United States appear to be the more common types, *L. icterohemorrhagiae*, *L. canicola*, and *L. pomona* in domestic animals and humans. However, 7 other serotypes have been isolated, and serologic findings suggest the presence of at least 2 others. The cause of "Fort Bragg" fever was identified as *L. autumnalis* 8 years after the initial outbreak (17). Six years later the first animal host for this type in the United States was detected when the organisms were isolated from the kidneys of raccoons trapped in southwest Georgia (18). *L. ballum* has been found frequently in rural house mice and opossums and occasionally in rats and laboratory mice (19,20). Recent evidence has shown that 1 proved and 7 probable human cases due to *L. ballum* contracted from Swiss white mice occurred among laboratory workers at the Public Health Service Rocky Mountain Laboratory, Hamilton, Mont. (21). Serologic evidence suggests the presence of *L. baturiae* infection in humans (22), *L. sejroe* in cattle (23,24), and *L. grippotyphosa* in humans (25) and cattle (23). During recent cultural studies at the Communicable Disease Center's Newton Field Station, Ga., on wild mammals, *L. grippotyphosa* was isolated from raccoons trapped within 60 miles of a Florida farm on which cattle showed antibodies to *L. grippotyphosa* in 1952. In addition, these studies have revealed the presence of *L. pomona*, *L. australis* A, three serotypes that belong to the *mitis-hyos* serogroup, one of which has been tentatively designated *L. bakeri* (16), and a member of the *hebdomadis* serogroup in wild mammals. It is notable that 61 percent of the leptospiral isolates from striped skunks proved to be *L. pomona*. The highest prevalence of infection has been found in the striped skunk, opossum, and raccoon although occasional isolations have been obtained from the spotted skunk, the gray fox, and the wildcat.

Although comparatively little attention has been directed toward the study of wild mam-

mals elsewhere in the United States, Reilly reported serologic evidence which suggested *L. canicola* infection in raccoons in New York (9), and Roth recently isolated *L. pomona* from opossums in Louisiana (26). In a recent survey of wild animal serums in Ohio by the divisions of wildlife and animal industry, Ohio Department of Agriculture (27), leptospiral antibodies against *L. pomona* were detected in 43 (19 percent) of 224 samples from deer, 16 (22 percent) of 70 serums from raccoons, 14 (25 percent) of 55 serums from foxes, and 6 (54 percent) of 11 serums from skunks. Current information regarding the occurrence of leptospiral serotypes in the United States is summarized in table 1 (28).

Transmission

In the transmission of leptospiral infections to humans, the animal carriers which may become urinary shedders after acute, mild, or more frequently inapparent infection, serve as important foci. Infections of humans and other animals result from direct or indirect contact with infected urine of these shedders. For example, direct contact may occur when people care for sick animals, fondle a pet dog, or handle the tissues of infected animals in abattoirs. Indirect contact occurs when the organisms are excreted in water or moist soil, and people are subsequently exposed while swimming, working, or otherwise coming in contact with the contaminated environment.

Although arthropod vectors have not been incriminated as yet in the transmission of leptospirosis in nature (29,30), several investigators have been able to infect ticks by allowing them to feed on infected guinea pigs or hamsters. These experimentally infected ticks transmitted the disease to normal animals. However, recently *L. grippotyphosa* was isolated from the European tick, *Dermacentor marginatus* S. from cattle in Russia where isolated cases of leptospirosis had occurred among farm animals (31).

During the acute phase of leptospirosis in lactating animals, leptospirae may be shed in the milk, but no human cases have been attributed to drinking infected milk. This may be explained by Kirschner's (32) observation that

whole milk is leptospiricidal and the organisms survive in it only a few hours.

The leptospires usually enter the body through the mucous membranes of the conjunctivas, nose, or mouth, or abrasions on the skin. It is doubtful that these organisms penetrate the intact skin, and it is unlikely that the digestive tract is an important portal of entry since the pH of the stomach is usually such that the organisms may be quickly destroyed.

Environments that favor the survival of leptospires outside the body include moist soil, stagnant ponds or slow-moving streams that are

neutral or slightly alkaline, and a temperature of 22° C. or above. When these conditions exist in nature, leptospires may survive several weeks (33,34).

Outbreaks and Sporadic Cases

Under such environmental conditions, several large outbreaks have occurred in the United States following swimming in contaminated water. Since 1940, there have been 4 outbreaks in Georgia (28,35,36), 1 in Alabama (37), and 1 in Wyoming (38) involving more than 150 in-

dividuals. All these waterborne leptospiral outbreaks followed a similar pattern. They occurred in the late summer during drought periods: there was presumed contamination of a stagnant pond or slow-moving creek by urine from infected animals and transmission to humans by immersion in the contaminated water. The patients were young, primarily children ranging in age from 5 to 16 years but also some young adults.

An outbreak of pretibial fever occurred among troops at Fort Bragg in August 1942 and again in the summers of 1943 (17) and 1944 (39-41). All patients were quartered in the same general area of the post. Many had been swimming in the nearby ponds but not all, so the source of their infection remains obscure. These reported outbreaks are summarized in table 2 (38).

An unusual family outbreak was reported recently by Hamz and Cardy (42). The family, including the parents and seven children 5 to 16 years of age, lived in a converted boxcar without sanitary facilities. Drinking water was kept in a bucket, and the family dog occasionally drank from this bucket. The dog was sacrificed and leptospire were demonstrated in sections of kidney tissue. All members of the family became ill within 1 month.

In recent years, reported human cases of leptospirosis in the United States have increased. Cases reported from 1905 to 1948 were summarized by Molner and his co-workers (43) according to geographic distribution. During this 43-year period there were 220 cases in 24 States, 8 cases unspecified as to location, and 78 cases in Michigan reported by these authors, making a total of 306 cases for the period.

In contrast, a summary of patients showing positive serologic tests in CDC's laboratories during a 5-year period (1953-57) plus cases reported to CDC by State health departments or to the National Office of Vital Statistics during this time revealed a total of 445 cases in 40 States. In addition, 94 cases occurred in outbreaks reported between 1951 and 1956 (fig. 1).

Occupational Hazards

The leptospiroses are frequently referred to as occupational diseases. Certainly, oppor-

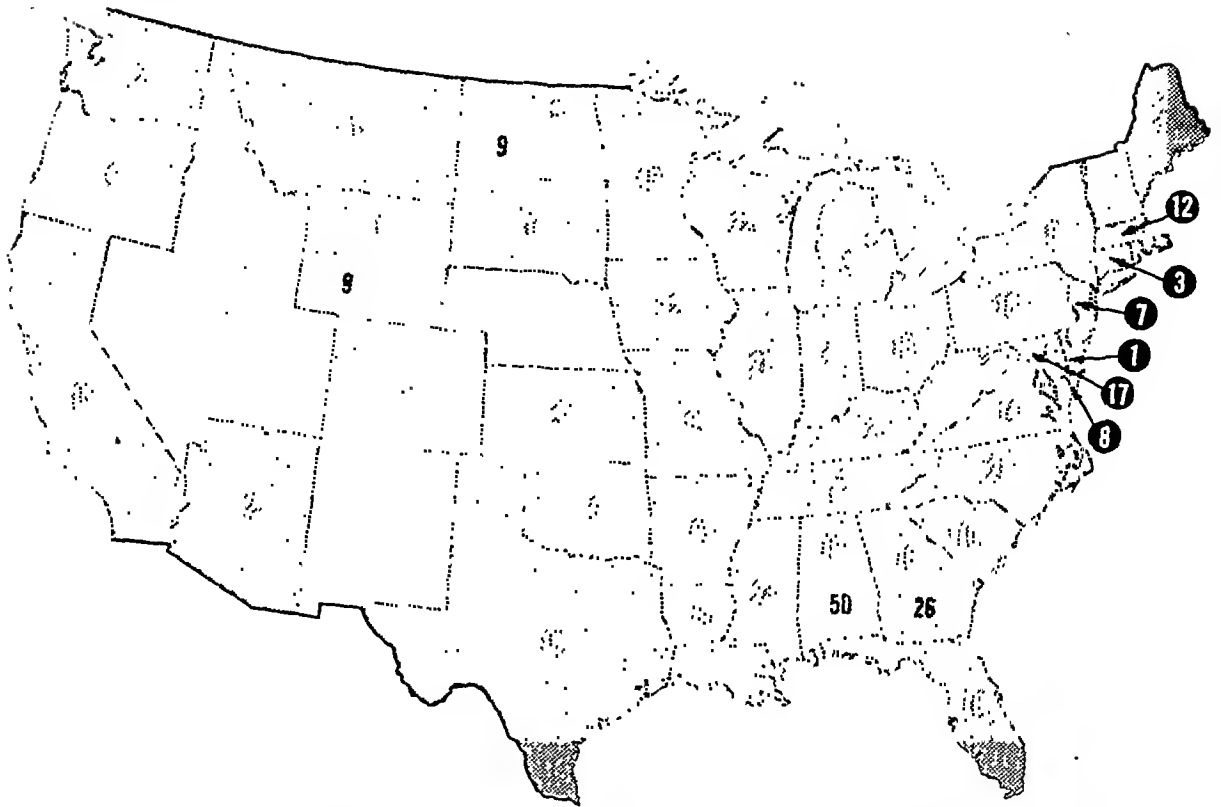

tunities for exposure are encountered more frequently by veterinarians, animal husbandrymen, swine herdsman, and workers in abattoirs, sewers, dairies, and poultry and fishhouses.

In Europe, Asia, and Australia leptospirosis is an important health and economic problem among agricultural workers, particularly in the ricefields and canefields (44,45). The apparent lack of this problem among agricultural workers in the United States may be attributed to higher living standards and to mechanization of agricultural operations. For example, in Italy the flooded ricefields are worked by hand laborers in their bare feet; in the United States the work is done mechanically. In the United States also, protective clothing, boots, or heavy shoes are usually worn to perform other tasks on farms requiring contact with contaminated soil.

During the past 4 years information has been obtained regarding 130 cases of leptospirosis that occurred in 30 States and the District of Columbia. Knowledge of these cases came primarily from serologically positive serums referred by State health departments to the Diagnostic Microbiology Unit, CDC. Subsequent inquiry to the State epidemiologists usually resulted in a history of the case. Others were reported by State health departments or the National Office of Vital Statistics, or they were investigated, on request, by the *Leptospira* Research Laboratory staff. Information concerning the probable source was obtained on 89 of the 130 cases. Of these, 32 (36 percent) had had contact with infected cattle or swine either in abattoirs or on farms; 23 (26 percent) had been drinking, swimming, or accidentally immersed in presumably contaminated water; 14 (16 percent) had had contact with dogs in their homes or in veterinary hospitals; 12 (13 percent) were exposed to rats; 3 (3 percent) to wild animals; and 5 (6 percent) to other animals or possibly contaminated environments in their occupation. Of these 5 individuals, 1 was a bulldozer operator, 1 a tractor driver, 1 a rice-field worker, and 1 had contact with an infected goat. The fifth person had been confined to a city jail for approximately 10 days prior to onset and may have had contact with infected rodents.

The fact that the probable source of more

Figure 1. Occurrence of human leptospirosis in the United States, 1953-57.

NOTE: 445 patients (white figures) showing positive serologic tests in CDC laboratories and cases reported by State health departments, 1953-57. 94 cases (black figures) reported in outbreaks, 1951-56.

than one-third of these cases was found to be contact with infected cattle or swine may be attributed, in part, to the rapid spread of bovine leptospirosis in the United States. York (46) reported occurrence of the disease in only 12 States prior to 1951. By 1956 it had been recognized in 42 States, according to data obtained from a summary of animal morbidity reports sent to CDC, published reports, and positive serum samples examined at CDC (28). In 1954 the Agricultural Research Service of the U. S. Department of Agriculture (47) estimated that annual losses from bovine leptospirosis were more than \$112 million, or \$25 million greater than losses from bovine brucellosis.

Since it has been estimated that 25 percent of the dogs in this country have or have had leptospirosis and 25 to 50 percent of these become temporary carriers, the opportunities

for exposure among children would be expected to be high, although Broom in England (48) observed a low infectivity rate among dog owners and their families. Recent investigations in the Leptospirosis Research Laboratory on leptospirosis in dogs in the Atlanta, Ga., area failed to detect leptospiral antibodies in serum from about 50 persons who had contact at home with 10 dogs infected with *L. canicola*. However, of the 14 persons with leptospirosis throughout the United States in which exposure to dogs was known, 10 had contact with sick pets in their homes and 4 worked in veterinary hospitals.

Age, Sex, and Seasonal Prevalence

As a result of environmental and occupational factors, the epidemiological pattern of human leptospiral infection has certain charac-

teristic features related to age, sex, and season. Although these infections may attack individuals of all ages, conditions are most favorable for infection of young adults. Beeson and Haukey (49) observed that the leptospiroses occur most frequently in the United States in males above the age of 15 years due to the occupational factor. In a series of 24 cases they found the age range was 10 to 55 years, but 19 (70 percent) were less than 30 years of age and only 5 of the patients were female. A distinct seasonal incidence was observed, with 10 (41 percent) of the cases occurring in August. Molner and associates (43) reported a similar age, sex, and seasonal distribution among 78 cases studied in the Detroit, Mich., area. In this series, 70 (90 percent) of the patients were more than 20 years of age and 73 (93 percent) were male, providing further evidence of an occupational relationship. Although sporadic cases occurred throughout the year, a definite increase was noted from August through November.

During the past 4 years the *Leptospira* Research Laboratory has gathered information on 130 cases of leptospirosis in 30 States and the District of Columbia. Patients ranged in age from 2 to 73 years, but nearly half were between the ages of 20 and 39 (fig. 2), and 88 percent were male. The highest incidence, 41 percent, occurred in the 3-month period from July through September (fig. 3).

Figure 2. Age distribution of 71 cases of leptospirosis in the United States, August 1954–May 1958.

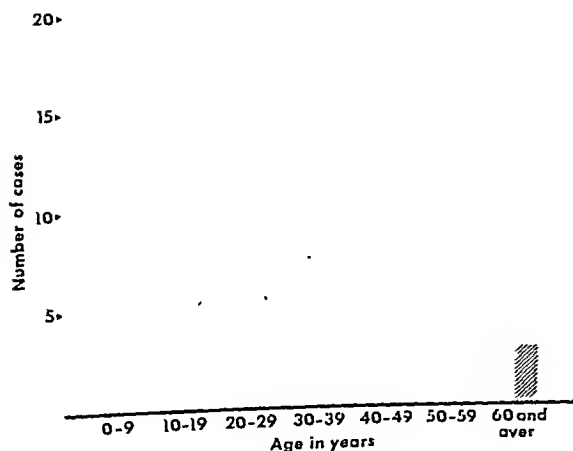

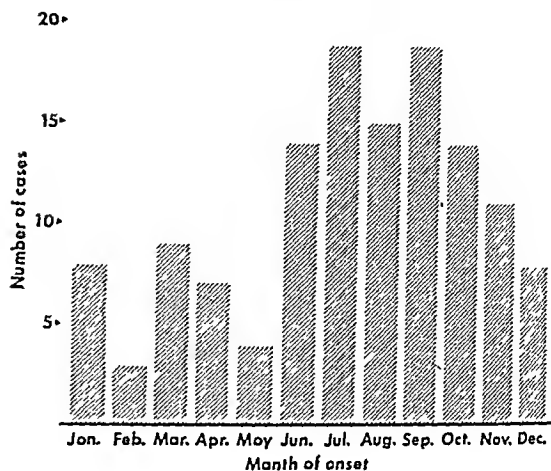

Figure 3. Seasonal distribution of 130 human cases of leptospirosis in the United States, August 1954–May 1958.

These observations regarding age, sex, and seasonal distribution of the leptospiroses in the United States are in accord with the findings of European investigators with possibly one exception. In certain agricultural areas where fieldworkers are predominantly women, there may be more women than men with leptospirosis (44).

Summary

The leptospiroses are a group of diseases caused by a variety of leptospiral serotypes. They are associated with a broad animal host spectrum and are transmitted from these animal carriers to other animals and to man. Transmission occurs by direct contact with infectious urine and with tissues of infected animals or indirectly through contact with contaminated water. The mucous membranes and abraded skin are usual portals of entry.

While *Leptospira icterohemorrhagiae*, *Leptospira canicola*, and *Leptospira pomona* have appeared to be the primary serotypes involved in human and domestic animal infections in the United States, the detection of serotypes hitherto unrecognized in this country emphasizes the need for public health, medical, and veterinary laboratories to search for them. Further study of the new feral mammal hosts will be necessary to determine prevalence of infection in other parts of the country and to determine their role

in the epidemiology and epizootiology of the disease.

Outbreaks have occurred in the United States and most other parts of the world as a result of swimming in ponds or slow-moving creeks contaminated by domestic or wild animal shedders. These outbreaks are usually observed during the late summer and affect primarily adolescents and young adults. Sporadic cases occur frequently from occupational exposures among veterinarians, abattoir workers, sewer workers, dairy workers, poultry and fishhouse workers, and animal husbandrymen. Information concerning the probable source of 89 human cases of leptospirosis that occurred in the United States from 1954 through 1957 revealed that 32 (36 percent) had had contact with cattle or swine either in abattoirs or on farms. The disease has been reported in the United States predominantly in young males in the 20-39 age group, and it appears more prevalent between July and November than in any other months.

Recognized cases of leptospirosis in humans have appreciably increased in the United States, and the disease in cattle has spread rapidly.

Control of Leptospirosis in Man and Animals

ROBERT W. MENGES, D.V.M., M.P.H.

COMPLETE control of leptospirosis in man depends on the elimination of the infection in carriers. After acute or, frequently, inapparent infections in domestic and wild animals, the organisms become established in the kidneys and may be shed with urine chronically. Urinary shedders of leptospire are primary vectors: the infection passes to other animals and to man by direct or indirect contact with infected urine.

Preventive measures have most often been aimed at the leptospire outside the body of its host (1). In the past, control methods pursued the destruction of the leptospire by chemical agents, heat, or desiccation; or they were designed to prevent the leptospire from gaining access to the susceptible host by ratproofing, confinement, or protective clothing. At present, immunization of susceptible populations and elimination of carriers by antibiotic treatment are being emphasized. In some instances, however, the best means of control may lie in the prevention of contact. For example, in the United States, most outbreaks of leptospirosis in humans (primarily in children and young adults) have occurred as a result of swimming in stagnant pools or streams contaminated by infected urine from animals. Notices placed in schools and service establishments might prove effective in warning swimmers of their risk.

Vaccines

Leptospirosis among certain occupational groups such as abattoir workers, dairy farmers, animal husbandrymen, veterinarians, sewer workers, plumbers, and miners may be con-

trolled by vaccination. Early investigators reported the excellent immunogenic properties of *Leptospira icterohemorrhagiae* killed with phenol (2), heat and phenol (3), and heat alone. In Japan, thousands of persons have been inoculated successfully with these vaccines. Babudieri (4) has controlled leptospirosis caused by *L. icterohemorrhagiae* and *L. bataviae* in ricefield workers in Europe by vaccinating with a formalized vaccine. The choice of serotypes in the vaccines was determined by the epidemiological situation. In countries where the disease is a serious problem, immunization of the population at risk has not been widely practiced.

Although vaccines have not been used for humans in the United States, their use in domestic animals is becoming quite commonplace. As a means of controlling the disease by establishing immune animal populations, vaccination holds great promise. The vaccines that have been developed include the egg-propagated *L. pomona* bacterin of York and Baker (5), and the culture bacterin of Brown and associates (6). Hoag and Bell (7) have described a soluble antigen which protected calves, and a strain of *L. pomona* attenuated through more than 500 egg-passages has been evaluated as an immunizing agent by Kenzy and co-workers (8).

From 1 to 3 weeks are required for the development of immunity following vaccination, and

Dr. Menges is a veterinarian in the Leptospira Research Laboratory, Epidemiology Branch, Communicable Disease Center, Public Health Service, Chamblee, Ga.

the duration of this immunity has been reported for periods varying from 18 to 20 months (8). Young calves may be protected by vaccination of the dams during late pregnancy (9) and young pigs by vaccination of the sows (10).

Stoerner (11) has suggested prompt vaccination of an entire herd when the disease is diagnosed early. Since leptospirosis may spread rapidly, any delay in vaccination would minimize the protective effect of the vaccine. If abortions or other symptoms of the disease have occurred for 3 or more weeks, an immunizing agent is of little value in preventing further losses. Herds of this category should be tested, and only serologically negative animals, replacements, and calves born during the next 6 months would require immunization.

Improvements in the vaccines are needed before general control by vaccination can be achieved. None of the vaccines currently in use provides protection against all the leptospiral serotypes that have been isolated from animals in the United States. The vaccines available for cattle and swine provide protection against *L. pomona*, and those for dogs, against *L. canicola* and *L. icterohemorrhagiae*.

Herd Management and Sanitary Measures

Herd management and sanitation have considerable value in prevention and control. The factors in general herd management which afford protection against leptospirosis include isolation of sick and aborting animals, provision of sanitary quarters that can be easily cleaned, and provision of sanitary feeding and watering conditions, with special emphasis on watering tanks that prevent contamination. New animals should be held in quarantine for a period of 1 month or more before they are introduced into the main herd.

When the disease is diagnosed during the early phase of an epizootic, Stoerner (11) recommends prompt alteration of husbandry methods to effect an environment unfavorable for the spread of infection. Feed and water should be given in a manner which would prevent contamination with urine. Natural streams or surface waters are readily contaminated with urine of recovered carriers and should not be used

as sources of water. Farm ponds located in pastures should be drained or fenced and the cattle should be watered from tanks. The aprons surrounding these tanks should be free of seepage or overflow. Roughage should be fed from portable racks which can be moved frequently. Whenever possible, crowding of cattle in confined quarters should be avoided. On dairy farms, milk from cows should be pasteurized before being fed to baby calves. Horses, swine, and cattle should be kept in separate pastures.

Treatment of Carriers

Curing carriers by treatment has been tried by several workers. Ringen and co-workers (12,13) reported on attempts to eliminate the carrier condition in cattle infected with *L. pomona* by dihydrostreptomycin and terramycin therapy. Their findings suggested that dihydrostreptomycin given intramuscularly at a level of 5 mg. per pound of body weight every 12 hours for 3 days eliminated the carrier state. They demonstrated also that 2.5 mg. of tetracycline hydrochloride per pound of body weight was the minimal dose, since the 2.0 mg. level failed to prevent the development of carrier animals. The tetracycline hydrochloride was given intramuscularly once daily for 5 days. Baker and associates (14,15) found that in swine, disinfection of urinary shedders was accomplished as a result of 7-day feeding of terramycin at 500 gm. per ton of rations. He concluded that a program of high-level, short-term terramycin feeding to pregnant sows and gilts would significantly reduce losses from leptospirosis. Brunner and Meyer (16,17) found that streptomycin and aureomycin were possibly effective in clearing the urinary carrier state of hamsters and dogs infected with *L. icterohemorrhagiae* and *L. canicola*.

Wild Animals

Vaccination and the use of antibiotics may aid in the control of leptospirosis in domestic animals, but these methods cannot be applied to leptospiral shedders in wild animal populations. This problem may be approached by two methods; active campaigns to destroy carrier

animals by trapping or shooting, or the destruction of the leptospires in contaminated soil and water by disinfectant agents. The method used will depend on the circumstances.

In Japan, Tokyama (18) applied calcium cyanamide as a fertilizer to some of the rice-fields in an area where Weil's disease was very common. As a result of this treatment, the number of cases of Weil's disease was markedly reduced. In the United States, Molner and co-workers (19) studied a poultry-dressing establishment in which 18 cases of Weil's disease had occurred. The premises were heavily infested with rats, and the worktables were incompletely cleansed of blood and offal at night. *L. icterohemorrhagiae* was isolated by washing the tables with saline in the morning and injecting this fluid into guinea pigs. When the tables were swabbed with diluted hydrochloric acid in the evening, similar inoculations failed to infect guinea pigs.

Laboratory Animals

Laboratory animals may also serve as a large reservoir of leptospires. *L. ballum* has commonly been found among laboratory white mice (20), *L. icterohemorrhagiae* among laboratory rats (21), and natural infection with this serotype has occurred among guinea pigs (22). In Europe, *L. grippotyphosa* has been isolated from naturally infected hamsters (23). Stoenner (24) has recently reported infection of eight laboratory employees who had close contact with Swiss albino mice which were infected with *L. ballum*. Control of the disease in laboratory animals involves recognizing and destroying the infected animals, or possibly curing urinary shedders by the use of antibiotics.

Conclusion

It may be quite some time before effective control measures are developed for leptospirosis in the United States. At the present time we are just beginning to recognize leptospirosis as a disease of public health importance. Before we can control the disease, its extent must be determined in each locality. More cultural studies must be conducted to determine the sero-

types present. After the serotypes and the animals that are important reservoirs are known, effective control measures can be instituted.

Summer Session in Health Statistics

A second training program in statistics applied to health sciences will be held from June 18 to August 1, 1959, by the University of Michigan Graduate School of Public Health in cooperation with the accredited schools of public health in the United States.

The program is made possible by a research training grant from the Division of General Medical Sciences, National Institutes of Health, Public Health Service.

The courses, for which academic credits are given, are designed to meet the needs of statisticians, epidemiologists, senior public health personnel, professional workers in the health sciences, graduate students in statistics and health sciences, teachers of public health statistics, and others interested in the subject matter to be covered.

The course titles are statistical methods in public health, management of health agency records, registration and vital statistics, biostatistics in the health sciences, demographic methods in public health, statistical methods in epidemiology, sampling techniques in the health sciences, advanced biostatistics in the health sciences, and statistical methods in biological assay.

For further information, write Dr. F. M. Hemphill, Director, Summer Program Statistics in the Health Sciences, School of Public Health, University of Michigan, Ann Arbor.

What We Know About Alcoholism in Industry

HARRISON M. TRICE, Ph.D.

FAR LESS is known about alcoholism as it affects on-the-job work experiences of the employee who is a problem drinker than is commonly believed. The cost of problem drinking employees to their employers, for example, has sometimes been described as an annual "billion dollar hangover." Significantly higher rates of on-the-job accidents and job absenteeism are attributed to the problem drinker as compared with the rates of nonalcoholic employees.

Evidence to back up these alleged work characteristics is nevertheless quite sparse. The simple truth is that what we do not know about the work experiences and behavior of problem drinking employees greatly exceeds what we do know (1).

There have been some scattered estimates in widely separated companies regarding the cost to the employer of problem drinkers. But these merely suggest that in some job situations such an employee is a costly personnel item while in others he is a relatively minor expense item. Furthermore, his work-related accidents have not been studied in any systematic fashion to discover whether his rate is any higher than that of nonalcoholic employees. Even absenteeism, about which most is assumed to be known, has not been effectively studied with

reference to such variables as job types, job status, and stage in the development of alcoholic disease.

Despite this general lack of substantial data about the work behavior of the employee with a drinking problem, some tentative descriptions of the work experiences of alcoholics can be made with a fair amount of confidence. Moreover, there is a slowly developing body of data that can be labeled "things we know less about" but concerning which some hunches are available, even though there are fewer data to back them up than those experiences we can describe tentatively. In short, we can classify what we know about the industrial aspects of alcoholism into data that give us some reasons to believe they are reliable, and data that are far less reliable, but which nevertheless provide us some basis for hunches.

The fact that early- and middle-stage alcoholics continue to work is the work characteristic on which we probably have the most substantial data. Of some 700 work histories of members of Alcoholics Anonymous I collected, only 4 members reported they did not work regularly during the middle phases of their alcoholism. There seems to be little doubt that the alcoholic works regularly while his malady is in its incipient and middle stages. Typically he continues on his job for years as the symptoms of compulsive drinking develop at a slow but steady pace. He gradually, almost imperceptibly, loses control of his drinking until he comes to the point where, once he begins to drink, he finds it almost impossible to stop voluntarily.

The symptoms of the early and middle stages

Dr. Trice is assistant professor, School of Industrial and Labor Relations, Cornell University, Ithaca, N. Y. He is one of the nonalcoholic members of the board of trustees of the general service board of Alcoholics Anonymous. The paper was presented at the Annual Health Conference of Pennsylvania, University Park, Pa., on August 19, 1958

that accompany this loss of control are not the dramatic ones of late-stage alcoholism which most people think of when they hear the term. Consequently, he is unrecognized as an alcoholic and continues to work actively at his job or profession even though he is well along the road to alcoholism. It is this unrecognized, covered-up employee with a drinking problem who constitutes an especially difficult personnel matter for management.

What are some of these early and middle symptoms (2)? Since the alcoholic drinks to experience a sense of physical and emotional well-being, he soon discovers he must drink a lot more than he did a few years before because it takes more liquor to get the same "glow." So he begins to drink everyone under the table, and his friends often observe how well he can "hold his liquor." Thus his consumption increases markedly. So do his periods of temporary amnesia. Dubbed "blackouts" or "pulling blacks," these are not periods of physical unconsciousness. They are drinking episodes during which the developing alcoholic appears to an observer much like any other relatively drunk person. The difference, however, is the inability of the early-stage alcoholic to remember what happened during the drinking episode. At first these blackouts are sporadic, but in a few years they become regular experiences.

During the early period he gains a good deal of prestige among drinking friends for these drinking exploits. His capacity to drink and his inability to remember what happened are often sources of group recognition for him; the feelings of well-being he gets from drinking are reinforced by group rewards. But gradually his drinking friends begin to think of him as different and he does, too. As a result, he develops a series of psychological symptoms.

He begins to hate himself for not having the willpower of others, and he finds in alcohol a temporary relaxation of this self-hate. But upon sobering up, he discovers the self-hate is still there, along with an energy-sapping hangover. So, unlike the nonalcoholic with a hangover, he turns to more alcohol in an effort to manage the twin agonies of emotional remorse and hangover pain. At the same time he begins an intense drive to refute the growing realization that he has a drinking problem.

His excuses for drinking become exaggerated, often bizarre. He vigorously denies there is anything wrong, frequently going to work when in bad physical and emotional condition just to prove it. He often seeks out persons who "drink like I do" in an effort to find a congenial set of friends who will not increase his guilt about his drinking (3).

Efficiency Decline

These symptoms usually have a direct impact on his work efficiency. It seems to be quite clear that the hangover, the self-hate, the preoccupation with denying there is anything wrong, the loss of control that leads to continued drinking off the job until something outside himself intervenes to stop him, and the anxiety about getting alcoholic relief during the workday reduce substantially his ability to do his job.

This decline in efficiency has numerous facets. The problem drinker begins to procrastinate a great deal, to put off everything except absolutely essential tasks, to fulfill only the immediate requirements of his job. He compromises with quality, accepting second or third "best" because he is unable to concentrate on the details necessary to perform his job well (4). A "don't-care" attitude supports the work slowdown. Fatigue saps his energy, and consequently initiative is forgotten. He has a strong tendency to do his job any old way just to get it done. In short, he is content with a mediocre performance. Because he becomes very guilt-ridden about his poor work, typically, he tries to make up for it by spasmodic spurts of output or creativity during which he often does superior work (5). This serves as a sign to him that his work is still well done. Actually it is merely a short-lived increase in a general efficiency decline.

Fairly good data also indicate that problem drinkers are rather evenly distributed through all occupational groups as well as many types of businesses and industries (6). The old stereotype that visualized the unskilled, poorly educated "drunk" as the typical alcoholic is obviously wrong. Company after company has discovered well-developed problem drinkers among their managerial ranks, and the pro-

fessions appear to be proportionally represented in the alcoholic population. In short, it seems that alcoholic employees appear in substantial numbers in managerial, skilled, unskilled, semiskilled, service, clerical, and professional occupations. When the last stages of alcoholism are reached there is some tendency to gravitate toward the migratory, spot-labor jobs, but this is far from a general trend even at this stage.

The middle-stage alcoholics are apparently rather evenly distributed throughout the various types of American industries (7). Construction does not seem to have an unusually low or high number of them in comparison with agriculture or manufacturing. Transportation has substantial numbers, as do finance and service businesses. Government service, including the military, has its quota but, again, not in any unusual concentration.

In addition to this characteristic of dispersion throughout the work world, the middle-stage alcoholic is, in many respects, like any other employee (6). He cannot be distinguished by his length of service, marital status, or mode of residence. Although his drinking deviates from accepted limits, he is still part of established social and economic patterns of living.

The type appears to be lodged heavily among male employees in the ages from 35 to 50 years. Certainly female alcoholics exist, probably many more than are currently estimated, and many more women are in the labor force today than 20 or 30 years ago. There are still good grounds, however, for believing that industry will find more alcoholism among men than women. Even more certain is the characteristic that alcoholism is a disorder of the mature years at a time of maximum work expectancy. If it were spread evenly among workers of all age groups, its industrial impact would be far less. Concentrated as it is in the productive years of 35-50, it can impair a large number of workers at the point of their greatest work contribution.

Company Rehabilitation Efforts

Numerous prominent companies have recognized alcoholism as a health problem, issuing

personnel policies regarding it and setting up specific procedures to carry them out (8). Typically, the policy statements issued (a) indicate that the company regards alcoholism as a form of illness and intends to act accordingly; (b) explain how the company will aid in the rehabilitation of the alcoholic employee; and (c) set the limitations on this aid, that is, the point at which the company will cease to aid in the rehabilitation of such an employee and consider his discharge.

In implementing these policies, various personnel practices have been used. Sickness benefits, pension eligibility, leaves of absence, counseling and referral to outside treatment facilities, and supervisory training relative to the malady have all been offered in various company programs for rehabilitation. However, no one company has used all of these. Most of the programs operate in the belief that rehabilitation does not occur overnight and that recurrence of drinking can be expected. When the employee makes a sincere effort and his "slips" become infrequent, most companies with rehabilitation policies believe there is justification for continuing company aid.

On the other hand, when reasonable aid does not produce or seem to prognosticate any basic change in the drinking pattern, most companies consider termination. Continued aid in rehabilitation under these conditions, they believe, is merely an unwitting support of abnormal drinking and is probably a hindrance rather than an aid to sobriety. Briefly, almost all companies with a treatment policy will, under certain circumstances, discharge an employee because of his drinking. A few companies exhaust all possibilities for every alcoholic, requiring special review before termination. This is especially true for longtime employees.

Extent and Cost to Industry

Data on the extent and cost of alcoholism in business and industry are far less reliable than data on efficiency decline and efforts at rehabilitation. There are grounds only for reasonable guesses. Estimates of the number of employed middle-stage alcoholics have been made in two ways: (a) by taking the estimated number of all alcoholics in the total population and making

an educated guess of the number who are regularly employed, and (b) by using the estimates made in specific companies as an indication of the number throughout industry. Both of these approaches are questionable at best; however, they provide us with a rough idea of the extent of the problem.

Estimates of the total number of alcoholics have come mainly from the Jellinek estimation formula (9), the intricacies of which I will not explain here. It is appropriate, however, to point out that numerous efforts to validate estimates made by the formula have shown considerable success. Thus, an independent survey of the number of alcoholics in a specific locality is compared with an estimation obtained with the formula. In numerous instances the two have agreed closely, leading to the tentative validation of the Jellinek estimations (10).

The chief difficulty with this procedure is that no one knows the accuracy of the independent survey against which the estimates were validated. The survey results may or may not correctly reflect the number of alcoholics in the area. Therefore, one set of questionable estimates may be validated against another set of equally questionable data.

On the other hand, the repeated close agreement between the appraisals made by the formula and independent assessment indicates that the Jellinek estimates are far more than conjecture. Apparently, there is a careful approximation in them that merits close attention. In 1955 the formula estimate was 4,500,000 incipient and full-blown alcoholics in the United States.

But how many of these are employed regularly in a definite job? Here the quest becomes very fuzzy. Most observers have played safe and said only half of these were actively employed. At the same time case histories of clinics and work histories of members of Alcoholics Anonymous suggest a substantially higher number in the employed category. But no one knows how to be more precise in any systematic fashion about the estimation.

The figure usually cited is 2 million, or approximately 3 percent of the Nation's labor force. But a particular company may have many more or many less than this percentage. Judging from studies in individual companies,

this figure can range from practically none to 10 percent (11,12).

But troubles in estimating really start when we try to appraise the costs of alcoholism to American industry and business as a whole. This appears to be not only an almost impossible task but also a gigantic one. When the vast array of factors, both tangible and intangible, affecting the value of an employee to his employer are considered, the difficulty of the task becomes obvious. And, when an effort is made to attach a dollar value to the way in which alcoholism reduces this value, any nationwide effort is extremely questionable. The best we can do is list the various cost factors that may be relevant to a particular company, leaving to the judgment of those who know the organization any actual estimation of dollar cost (13).

First, cost of reduced work efficiency is the most apparent factor. This can take many forms such as scrap, spoilage, errors in assembly and shipping, slowdown, fewer sales, increased rejects, and customer complaints. Executive and professional error adds another and even more costly dimension. Second, since many alcoholics appear to have a substantially higher absenteeism rate, they can be costly from this standpoint. Furthermore, companies make training investments in many employees which are lost if termination for alcoholism occurs, and replacing an employee can be expensive. The public relations impact of an alcoholic employee is also a potential cost item along with the sickness support the company may provide for the many related illnesses that accompany alcoholism.

Briefly, the only meaningful cost items come from specific companies who appraise alcoholic employees in specific jobs and attach a dollar value to their cases. This procedure has been attempted in a few instances, and the results suggest that in many situations problem drinkers are very costly to their employers, while in others the cost is relatively modest (14).

Absenteeism and On-the-Job Accidents

Again, we do not have very much specific information about absenteeism and on-the-job accidents of alcoholics. There are data indicating that, in general, the absenteeism rate of

a company's problem drinkers is significantly higher than that of nonalcoholic workers (15,16). Beyond this we have only hunches. However, these suspicions are interesting.

Some grounds exist for believing that "no-report" absenteeism and "partial" absenteeism characterize a developing drinking problem in an employee (17). Failure to report his inability to be on the job is often a symptom of the middle-stage alcoholic that distinguishes him from the average absentee. In the early stages, a member of his family may report his absence. But as his problem worsens, his absences will occur without advance notice from anyone. Often he comes to the job only to leave before the day is over (18). He realizes he cannot get through the day without a drink, so he leaves. This behavior is most likely in unskilled and semiskilled work which operates on a definite schedule and under close supervision.

There is also some exploratory evidence regarding absenteeism among high-status as contrasted to low-status problem drinkers (19). Alcoholic executives, engineers, lawyers, doctors, and other high-status workers apparently have substantially less actual absenteeism than do low-status alcoholics on semiskilled and unskilled jobs. High-status inebriates, however, seem to have a great deal of "on-the-job absenteeism," that is, they come to work when they feel bad from their drinking behavior, but for all practical purposes are "absent." They put in an appearance but merely go through the motions of doing their jobs. Low-status problem drinkers tend to have large amounts of actual "stay-away absenteeism."

Various motivations and work situations seem to account for this difference. The high-status alcoholics, despite their disorder, were motivated to go to work by a sense of responsibility, a desire to deny there was anything wrong, and as a way to reduce their guilt about excessive drinking. The motivations to go to work anyway were reinforced by the fact that once at work, they could get a drink rather easily when they wanted one. They have freedom from close supervision, freedom of schedule, and freedom to move around. Low-status workers did not express these motiva-

tions nor enjoy these job freedoms, so their actual absenteeism was consequently higher.

Far more contrary to popular belief are notions about the job accidents of the problem drinker. The belief that his accident rate must be higher than that of other workers is widespread. Yet what meager evidence there is suggests no such sharp difference (17,20). Reasons for this evidence to the contrary are numerous. Many jobs involve little exposure to accidents, and safety engineering has removed the dangers from many more. Problem drinkers, scattered throughout all occupational levels, have their share of the safe jobs. Also, the repetitive nature of many jobs and the routine to which an experienced employee reduces his work are a protection to the problem drinker.

Furthermore, an overcautious attitude is part of the problem drinker's defense mechanism. He seems to be overly cautious of job hazards and thus minimizes the chance of accidents. The problem drinker has a keen awareness of alcohol's effect on him and develops a routine for handling it. Finally, two factors act to reduce his actual exposure to accidents. On many days when he believes he is likely to have an accident he resorts to absenteeism; it is impossible for him to have an accident on the job if he isn't there. And, in some instances, fellow workers or a supervisor will see to it that a problem drinker is put on a safe job until he is in better shape to handle a job that exposes him to accidents.

Summary

Although evidence is rather meager, we know the problem drinker is a definite personnel problem for employers. Even though he is only in the middle stages of his malady, not a full-blown, chronic alcoholic, his work efficiency is materially damaged, and often he can be a definite financial liability. Alcoholism in industry is a disorder of the mature years, the time of maximum work expectancy.

Conservative estimates of the number of employees who are alcoholics center around 2 million, and there seems to be good evidence that they are present in substantial numbers in all occupational and industrial groups.

Something is being done for this type of employee. Numerous companies have a definite rehabilitation policy with specific procedures for implementing it. Most companies with a policy concerning treatment will, under certain circumstances, discharge an employee because of his drinking.

The inebriate with a high-status job has more "on-the-job absenteeism" than the low-status worker. There is little evidence that the accident rate for the problem drinker is higher than that of other workers.

A start has been made on developing more accurate data about such work experiences as accidents, absenteeism, and coverup. In short, what we know about the industrial aspects of alcoholism is slowly increasing. Soon we may be able to describe the job aspects of alcoholism more accurately.

Trichinosis in the United States

IRVING G. KAGAN, Ph.D.

AMONG all the intestinal nematodes, *Trichinella spiralis* has probably made the best adjustment for a parasitic existence. All stages of the life cycle are parasitic. The sexually mature worms reside in the small intestine and produce larvae which invade the musculature and internal organs of the host. A recent study of 55 experimentally infected hogs revealed the following distribution of larvae in the tissues: diaphragm, 100 percent; stomach, 18 percent; testes, 15 percent; liver, 11 percent; brain, lungs, wall of the small intestine, each 9 percent; pancreas and aorta, each 8 percent; and heart, 2 percent (1).

The definitive hosts for this parasite are usually carnivorous mammals, that is, those that eat the flesh and internal organs of infected animals. A survey of 2,433 mammals representing 42 species in Alaska revealed an incidence of infection of 11.7 percent in 23 species (2). Some of the infected hosts were aquatic mammals such as seals and white whales, which are primarily fisheaters, indicating that the epidemiology of *T. spiralis* may involve transfer or transient hosts.

In the United States trichinosis is a disease of man and his domesticated pig as well as a sylvatic disease of many wild animal species. A survey of trichinosis from 1953 to 1955 in Iowa emphasizes the sylvatic nature of this disease. Infected with trichinosis were 14 of 119 rats, 31 of 308 foxes, 1 of 40 opossums, 2

of 29 raccoons, 12 of 85 mink, and 2 of 4 coyotes. Examination of 2,184 pigs revealed 1 infection, and 18 of 1,148 pork products contained trichina larvae (3). In the arctic areas the polar bear, dog, and wolf are heavily infected.

The incidence of trichinosis in the American population is not accurately known today. Gould believes that a conservative estimate would place the figure at about 16 percent. But in a postscript he states that the incidence is probably more than double this amount (4,5). This means that 25 to 50 million Americans carry trichina larvae in their muscles and internal organs. A majority of these infections are symptomless and subclinical. Although most States do not make trichinosis a reportable disease, between 200 and 300 cases are reported each year to the Public Health Service. These are the recognized cases. Clinically, trichinosis has all the earmarks of so many other diseases that in all probability a large number of cases go undiagnosed. The mortality rate for recognized clinical cases was, approximately 5 percent in the United States (4,5).

The epidemiology of this disease is very well understood. We know how it is transmitted to man, and we know how to prevent its spread in the swine population. We are improving serologic diagnosis in the suspected patient and have made important advances in the treatment of the disease with ACTH and cortisone. In recent years two comprehensive national conferences on trichinosis were held in Chicago, the first in December 1952 and the second in March 1954. The many facets of the control of this disease were adequately covered in the papers presented at these meetings. In this paper I shall outline the problem and review

Dr. Kagan, chief of the Helminthology Unit, Communicable Disease Center, Public Health Service, Atlanta, Ga., presented this paper at the CDC Conference for Teachers of Veterinary Public Health and Preventive Medicine, and Public Health Workers, Atlanta, June 12-18, 1958.

some of the contributions that have been made since those meetings.

Control Measures

Trichinosis in the United States is perpetuated in a very small proportion, 0.63 percent, of the swine population through the feeding of infected scraps of pork collected in garbage (6). As of May 31, 1957, the Animal Disease Eradication Division of the U. S. Agricultural Research Service reports that 12,423 farms were feeding garbage in one form or another to swine. Hundreds of communities in the United States sell their garbage and use the funds for civic purposes. It is generally conceded that the prohibition of garbage feeding would drastically cut the incidence of trichinosis in the domesticated pig, but it would probably not eradicate the parasite because of the sylvatic incidence of trichinosis in rats and other scavenging species. The lone infected pig in the Iowa survey (3) may well have acquired trichinae by eating a dead infected animal on the farm.

Since a \$50 million industry, the collection and use of garbage for swine production, involving approximately 35 percent of the communities of the United States, probably cannot be legislated out of existence, attention has been directed toward another measure, the sterilization of garbage by cooking (7). Every State has some type of law or regulation which prohibits the feeding of raw garbage to swine. Garbage cooked at 100° C. for 30 minutes is freed of living trichina larvae. Approximately 11,747, 94.5 percent, of the 12,423 premises feeding garbage to hogs, report that they are feeding cooked garbage. This salutary situation with respect to the use of cooked garbage was engendered mainly by the necessity of preventing the spread of garbage-borne epidemic disease of pigs, such as hog cholera, vesicular exanthema, foot-and-mouth disease, salmonellosis, tuberculosis, swine erysipelas, and brucellosis. Because of noncompliance by some farmers, the lack of adequate inspection facilities by some State agencies, and the expense of cooking garbage, the control of trichinosis by this method has not been completely successful. Continued education, research, and law en-

forcement by State and Federal officials will do much to strengthen this very effective method of trichina control.

Inspection of pork products constitutes another means of control. The Federal Government requires that "the respective States allow the sale of garbage-fed hogs for slaughter only at a federally inspected plant or plant having equivalent inspection." In some countries tissue press preparations of each carcass are carefully inspected microscopically for the presence of trichina larvae. In Chile a staff of 22 persons is necessary to process and examine 1,000 pigs a day: 8 trichinoscopists, 4 sample collectors, and 10 assistants preparing 8 slides from each carcass for examination (8). It is estimated that an effective program of microscopic inspection in the United States would cost more than \$40 million (9). For this and other reasons, the microscopic examination of pork has not become a routine procedure in our country.

The freezing of pork is also advocated for killing trichina larvae in infected carcasses. As early as 1914, research by the U. S. Bureau of Animal Industry indicated that refrigeration of pork at -15° C. (5° F.) for 20 days is an effective safeguard against trichinosis in man (10). These studies were the basis for the present practice of holding pork and pork products customarily eaten without cooking by the consumer for 20 days at 5° F., 10 days at -10° F., or 6 days at -20° F. In Canada pork is held at -15° C. for 3 weeks in sealed storage lockers inspected by the government (11). Quick freezing at temperatures of -37° C. (-34.6° F.) kills trichina larvae in 2 minutes. In the United States today meat packing plants do not have the space to freeze and store the huge volume of pork processed. The cost to the consumer for freezing pork would be approximately 5 cents per pound. This economic factor plus consumer resistance to the purchase of pork that has been frozen and thawed make this type of control impractical and difficult to initiate (12).

Sterilization of carcasses by irradiation has been carefully investigated by Gould and his co-workers (13). These workers have estimated that facilities using cesium-137 as the source of radiation, costing in excess of \$500,000, can

effectively treat carcasses with 30,000 roentgens, enough radiation to make the larvae incapable of completing their life cycle in the host. The cost to the consumer is estimated at 0.23 cents per pound, and the meat is said to be unaltered, healthful, and palatable.

The most effective and the cheapest control method is the thorough cooking of pork by the consumer. If they were aware of the hazards, many persons would not eat uncooked pork or pork products that have been smoked and not adequately heated prior to processing. Informing the producer on the farm about the dangers of feeding raw garbage to his swine and alerting the housewife, food handler, restaurant owner, and others to the dangers of eating pork not thoroughly cooked are among the control measures recommended by previous conferences on trichinosis. But it should be reiterated that placing the responsibility for control of trichinosis on the consumer is not the most efficient method for controlling the disease.

Treatment and Diagnosis

One aspect of the epidemiology of trichinosis should be emphasized. Eradication cannot be accomplished solely by control measures initiated by the large farmer or food processor. A number of trichinosis outbreaks have been traced to pork products that did not pass through federally inspected plants (14). The small farmer with a few pigs which are fed table scraps (uncooked garbage) and butchered in local abattoirs account for some of the incidence of trichinosis in the United States.

Since so many trichina infections are subclinical, the question has been raised regarding the necessity of any kind of control. Magath and Thompson believe that persons infected with small numbers of trichina larvae have an acquired immunity which would be destroyed were the disease controlled (15). From a public health point of view such a position is untenable. We must strive for the control of all communicable diseases. There is also to be considered another facet of this complex problem that has received very little attention—the evaluation of the deleterious effects of a subclinical infection in an individual. In the rat, infection with trichina larvae reduces the work-

ing ability of the animal 49 to 60 percent. Weight loss induced by exercise is 150 to 170 percent greater than in the controls (16).

Little attention has been directed toward the use of long-lasting, broad-spectrum chemotherapeutic agents administered in the feed to eliminate *T. spiralis* adults and other intestinal roundworms in swine. In mice, medicated feed containing 0.15 percent cadmium oxide produced a striking reduction in the number of adults and larvae harbored by infected animals (17).

The use of a skin test for the diagnosis of infection in pigs has not received much attention in recent years. Soulsby skin-tested animals in England and reported cross-reactions with *Ascaris* infections (18). With the application of newer immunochemical techniques, specific antigens could be prepared for this purpose.

Two flocculation serologic procedures are available for the diagnosis of trichinosis: the method of Sussenguth and Kline (19), utilizing cholesterol particles, and the bentonite technique of Bozicevich and others (20). The Helminthology Unit at the Communicable Disease Center uses the bentonite flocculation test for the diagnosis of trichinosis. We have found this method effective in detecting antibody during acute infections in man and animals. In an experiment with experimentally infected hogs, flocculating antibody was detected from the second to the sixth week of infection in all animals. After the ninth week antibody could no longer be determined (21). As a method of diagnosing active infection, the bentonite technique is excellent, but, for the detection of chronic infections, it does not compare with the technique of Sussenguth and Kline. These workers reported that antibody may be detected in infected hogs 1 year after infection (19). Utilization of a rapid serologic technique for the detection of infected animals prior to slaughter might under some circumstances be a useful control procedure.

Conclusion

To be successful, any control program for trichinosis must not conflict with the economics of pork production on the farm or at the proc-

essing plant. The control of trichinosis has benefited more from the measures taken to control vesicular exanthema than from all the recommendations made for the helminth disease. This is heartening because any measure taken against the spread of a garbage-borne virus disease will benefit a helminth garbage-borne disease. Although it may never be economically feasible to quick-freeze all pork in order to kill trichina larvae, the storage of pork in freezing compartments of refrigerators and home freezers is doing much to lower the incidence of trichinosis in our country (12).

In the not too distant future, we will have to come to grips with the control of this disease. Control will come when the American people are willing to pay the price of consuming trichina-free pork. Until that time the scientific community must continue working on more efficient methods of control and on instructing the public in methods of protecting its health and well-being.

Synchronizing the Roles Of State Agencies For Traffic Safety

ALBERT L. CHAPMAN, M.D.

SEVERAL years ago I began talking to State and local health workers about traffic accidents and their prevention. There appeared to be a consensus that traditionally this was the business of police officials and traffic administrators.

But when I asked the State motor vehicle administrator of a heavily populated eastern seaboard State whether he thought public health workers had a role to play in traffic safety, his answer was direct and very much to the point. This was the gist of his reply:

"The problem of traffic accidents is so great, we traffic administrators need all the help we can get. We can't take a high-risk driver off the road until there is scientific proof that he is a high-risk driver. We seldom have that proof. We need it badly. At least in the case of drivers with chronic illnesses and disabilities, it would be helpful to have the cooperation of the public health and medical professions in evaluating the degree of risk involved in giving a license to a driver who has such a disease as diabetes, heart disease, or epilepsy."

He quickly pointed out, however, and I believe rightfully, that "motor vehicle administrators and police officials did not want health people trying to run the show."

In short, there is a role for public health workers and physicians in traffic accident prevention . . . and an important role.

In the spring of this year, Dr. James L. Goddard, chief of the Accident Prevention Program in the Division of Special Health Services, Pub-

Dr. Chapman, an Assistant Surgeon General and chief of the Division of Special Health Services of the Public Health Service, presented this paper at the meeting of the Association of State and Territorial Health Officers in Washington, D. C., on October 23, 1958.

lic Health Service, working closely and cooperatively with Basil R. Creighton, assistant executive director of the American Association of Motor Vehicle Administrators, arranged for a 2-day conference between 8 State health officers and 8 State motor vehicle administrators and a few other officials.

It was a very successful conference. Almost within minutes it was realized that State health officers had remained aloof from the problem of traffic accidents in many States on the mistaken assumption that they had no stake in them. And the traffic administrators realized that there were many types of help that they could have obtained if they had sought the assistance of State health departments. Never before have I attended a conference in which two previously unacquainted groups of people worked so single-mindedly toward a common objective.

Because of this singleness of purpose some very constructive recommendations stemmed from the conference. It was suggested, for example, that the relationship of the two agencies in each State be explored by the Public Health Service and that a report of the findings be made available to the American Association of Motor Vehicle Administrators and to the Association of State and Territorial Health Officers.

A sample of some of the facts gleaned from this report shows current participation by State health officers in traffic safety and indicates ways in which they may be able to contribute further.

- State health departments hold membership on only 23 of the 42 governor's committees on traffic safety.

- In only 4 States are cases of diabetes and epilepsy reported by physicians to State health departments. In only 7 States do physicians report cases of these diseases to the State motor vehicle administrator.

- In only 1 State are mental patients reported to the State health department, and in only 10 States are such reports received directly by State motor vehicle administrators.

- Death certificates are sent to motor vehicle administrators by State health departments in 15 States, so that licenses are no longer recorded in the name of dead people.

- In 17 States, cooperative studies are being conducted by the State health department and the State motor vehicle agency. In 12 of these

States these cooperative studies are associated with the Cornell Automotive Crash Injury Research.

Suggestions for improving cooperation between State health departments and motor vehicle administrators follow.

Driver Licensing

The responsibility for advising State motor vehicle administrators concerning criteria that can be used to limit the driving privileges of persons who are suffering from diseases that may make them high-risk drivers is clearly a medical responsibility in which the entire medical profession must share. The State health department is the logical medium for bringing the State medical association and private physicians actively into the picture.

The weighing of the merits of reporting patients with diabetes, epilepsy, and heart disease to motor vehicle agencies is not a responsibility that should be sidestepped by the medical profession. As in all other problems involving doctor-patient relationships, there are two sides to this question. But serious consideration should be given to the merits of this activity by State health departments and medical societies.

Communication

Whether communication between the State health officer and the State motor vehicle administrator is established and maintained via a governor's traffic safety committee, frequent informal meetings between representatives of the two agencies, a system of regular, frequent exchange of reports, or through working together in cooperative studies, great improvement in the quality as well as the quantity of communication is essential.

Research

Epidemiology long has been considered the domain of health departments. As long as so little is known about the personal factors that contribute so substantially to traffic accidents, it would seem reasonable to expect most State health departments to follow the lead of the New York State Health Department, the California State Health Department, and others in

devising, conducting, and supporting epidemiological studies that can give us some of the many answers we now lack concerning driver accident susceptibility. And finally, there remains this question, which State health department personnel, physicians, police officials, and motor vehicle administrators will have to find the answer to: When you have identified the high-risk driver, how do you get him off the road?

Education

There are many facts known to science which, if communicated successfully to the driving public, could reduce the toll of traffic accidents. For example, facts about:

- The effects of drugs, such as the antihistamines, on driving ability.
- The effect of alcohol on reflexes and judgment.
- The effect of fatigue on reaction time.

In addition, there is a vast field ripe for study and investigation by medical and paramedical personnel:

- The effect of emotions on driving ability.
- The personality pattern of chronic traffic violators.
- The motivations of persons who drive in an irresponsible fashion.

The modern American car, although not perfect from the standpoint of safety design, is still a miracle of scientific achievement. Relatively few accidents occur primarily because of mechanical faults or failures.

This cannot be said of American drivers. Almost anyone is permitted to drive a car today under any and all conditions. While our scientists have been busy harnessing the atom, and medical scientists have been successfully confining once epidemic diseases such as malaria and poliomyelitis, relatively little time, money, or attention has been spent in determining the basic reasons why 40,000 Americans are killed by automobiles each year.

To me, all of this is a challenge which has been inexcusably evaded by the rank and file of the public health and medical professions for several decades. The question now is: What are we going to do about it?

Spontaneous Diseases and Their Control in Laboratory Animals

ROBERT T. HABERMANN, D.V.M.

THE NEED for laboratory animals that are free from spontaneous or naturally occurring diseases is being recognized by research workers throughout the United States. Laboratory animals with parasitic, bacterial, and viral diseases make poor experimental animals, produce inferior biological products, and markedly increase the cost of research. Moreover, diseased animals should not be used in research, especially in radiation, nutrition, and blood studies, because the normal physiological reactions or blood counts are not obtained from them. Researchers know that the results of experiments are reliable, trustworthy, and repeatable only if disease-free animals are used.

During the past 10 years, the Comparative Pathology Section and the Animal Production Section of the National Institutes of Health, Public Health Service, have investigated some of the diseases occurring naturally in mice, rats, guinea pigs, rabbits, and hamsters. The purpose of these investigations was to determine the diseases most injurious to these animals and to evaluate some of the methods of disease control and eradication.

External and Internal Parasites

External parasites cause or transmit some inflammatory skin disorders and parasitic and bacterial diseases in laboratory animals. Alopecia and dermatitis may be caused by the biting and sucking of lice, fleas, and bedbugs or by the burrowing of some species of mites. Eperythrozoonosis, transmitted by the mouse louse *Polyplax serrata*, produces a mild anemia in

mice. It is caused by *Eperythrozoon coccoides*, a gram-negative, disk-shaped organism that occurs in the plasma and on the red blood cells. The rat louse *Polyplax spinulosa* transmits bartonellosis, caused by rod and coccoid-shaped organisms, *Bartonella muris*. They produce a severe anemia in splenectomized rats.

The intermediate or larval stage of the tapeworm *Hymenolepis nana* is transmitted to mice and rats by ingestion of fleas and meal beetles.

To eliminate these external parasites and control insectborne diseases, we used an insecticide consisting of 0.1 percent gamma benzene hexachloride, 2.0 percent methoxychlor, and 97.9 percent talc. The animal care workers at the National Institutes of Health have used more than a ton of this insecticide, and no deleterious effects due to the medicated powder have been reported.

Benzyl benzoate is effective in treating and controlling ear mange, or ear canker, a common parasitic infestation of rabbits. This inflammatory condition, usually confined to the external ear, is caused by a mite, *Psoroptes cuniculi*.

Diarrhea and death in young rabbits are frequently caused by two species of coccidia.

Dr. Habermann is veterinary pathologist with the Comparative Pathology Section, Division of Research Services, National Institutes of Health, Public Health Service. This paper was presented at the Communicable Disease Center Conference for Teachers of Veterinary Public Health and Preventive Medicine, and Public Health Workers, Atlanta, Ga., June 12-18, 1958.

Eimeria perforans causes intestinal coccidiosis and *Eimeria stiedae*, hepatic coccidiosis. We eliminated these two protozoan diseases from the rabbit colony by screening for infection through saltfloatation fecal examinations and either removing the infected animals from the colony or giving them a saturated solution of sulfaguanidine in their drinking water for a 2-week period. Sanitation and the washing of all green vegetables are also important preventive measures. Since April 1955, after these procedures were adopted, only 12 positive coccidial fecal samples have been obtained in more than 1,400 examinations.

Tapeworms *H. nana* and *Hymenolepis diminuta* are the two common cestodes found in mice and rats. Treating groups of animals by adding 50 mg. of lead arsenate to 20 gm. of ground mouse feed and 100 mg. of the drug to 20 gm. of ground rat feed is effective. Culbertson (1) reports that 10 mg. of atabrine by mouth for 2 successive days is also effective.

The oxyurids, or pinworms, of mice and rats are *Syphacia obvelata* and *Aspicularis tetraptera*. These worms occur in the cecum and colon and produce a catarrhal enteritis when present in large numbers. A dose-rate per mouse of 40 mg. of piperazine adipate in 10 cc. of drinking water and a dose-rate per rat of 250 mg. in 50 cc. of water for 3 days for both mice and rats was found to be 95 percent effective in removing oxyurids from mature animals. Females and their litters should be re-treated in 30 days to remove pinworms from unweaned mice that were unable to drink the medicated water.

Although no critical anthelmintic tests have been run, we believe that the piperazine compounds would also be effective in removing the roundworm *Paraspidodera uncinata* from guinea pigs and the pinworm *Passalurus ambiguus* from rabbits.

The larval forms of the tapeworms of the dog and cat are occasionally encountered in laboratory animals. *Cysticercus fasciolaris*, the larval stage of *Taenia taeniaformis*, the tapeworm of the cat, appears in the livers of mice and rats. *Cysticercus pisiformis*, the larval stage of *Taenia pisiformis*, the tapeworm of the dog, is attached to the mesentery of rabbits.

Protozoa which may cause diarrhea and catarrhal enteritis are *Balantidium cavae*, a ciliated protozoan occasionally found in the colon of the guinea pig, and *Trichomonas* spp. and *Giardia* spp., frequently found in the cecum and colon of the hamster.

Salmonellosis

In the absence of an effective vaccine or therapeutic agent for the control of salmonellosis, research workers must rely on strict sanitation and general preventive measures to avoid the introduction and spread of this disease in laboratory animals. Prior to 1954, *Salmonella* spp. were frequently isolated from the organs and feces of the laboratory animals at the National Institutes of Health. In 1954, approximately 38,000 mice were screened and examined for salmonellae by bacteriological examination of composite fecal samples using the procedures outlined by Galton (2). In 1956 no salmonellae were isolated from the fecal samples of 2,800 mice, 1,000 rats, 800 guinea pigs, 1,200 rabbits, and 200 hamsters. During the same period in 1956 salmonellae were isolated from 25 monkeys (14.1 percent) of 177 in the colony. In 1957 salmonellosis was not observed in necropsies of more than 4,000 laboratory animals.

That year bacteriological examinations for *Salmonella* spp. were run on 780 samples taken from unopened bags of animal feed and 125 samples of sawdust used by the Animal Production Section. In 375 samples of mouse and rat feed *Salmonella kentucky* (identified by Dr. P. R. Edwards) was isolated from 1 sample; *Escherichia coli* from 7; coliform organisms from 77; paracolon bacilli from 14.

No salmonellae were isolated from 375 samples of the guinea pig and rabbit feed, but *E. coli* was found in 9 samples, coliform organisms in 6, paracolon bacilli in 1.

Organisms isolated from sawdust were *E. coli* from 25 samples, coliform types from 42, and paracolon bacilli from 8.

No organisms were found in samples of heated feed: 9 samples of dog feed, 6 of monkey biscuits, 3 of guinea pig pellets, and 12 of dog chow. These examinations showed that although salmonellae were isolated only once

from the unheated animal feed, fecal contaminated feed and sawdust are possible sources of salmonellosis in an animal colony.

Chronic Respiratory Disease

Chronic respiratory disease, the infection most injurious to laboratory rats, is prevalent in all rat colonies unless disease-free animals have been obtained from outside sources. Early lesions from the naturally occurring disease are seen in 3-month-old rats, and, as the animals get older, the lesions become more extensive.

In most rat colonies approximately 70 percent of the animals past 1 year show rhinitis, middle ear infections, bronchiectasis, and abscesses of the lung. Nelson and King (3,4) have reported that infectious catarrh and middle ear infection are caused by pleuropneumonia-like organisms (PPLO) and *Streptobacillus moniliformis*, and that the etiological

agent of endemic pneumonia is a filtrable virus (5).

In October 1955, we began a long-term experiment to study methods of control and treatment of chronic respiratory disease in rats. Eighteen female and nine male rats were selected from three 60-day-old litters. These animals were divided into 3 groups, each containing 6 females and 3 males. One group was offered chlortetracycline at the rate of 5 mg. per 20 gm. of feed daily; the second group, 5 mg. of sulfamerazine per 20 gm. of feed daily; and the third group, 20 gm. of unmedicated ground feed daily. Necropsies and histopathological examinations were conducted on the original 27 rats and the 5- to 11-month-old progeny through the fifth generation, a total of 175 animals.

At necropsy, the animals in each group were examined for exudates in the nasal passages and middle ears and for involvement of lung lobes. Exudates from the nasal passages, middle ears,

¹ Microscopic results not completed.

NOTE: The control group received 20 grams of unmedicated feed daily; the second group received a daily dose of 5 mg. of chlortetracycline per 20 grams of feed, and the third group 5 mg. of sulfamerazine.

and from lung lesions were collected, gram-stained films of exudates were made, serum agar plates were inoculated, and disease-free mice were inoculated with the suspension of the exudates, according to the procedures outlined by Nelson (5).

The table shows the results of the necropsy findings from the 27 original animals and their 148 progeny. Each group of the original breeders showed very little improvement from the treatment. The control group contained 2 rats with areas of consolidation and bronchiectasis. In the sulfamerazine group, 1 animal showed bronchiectasis and consolidation of the lung, and the chlortetracycline group contained 7 rats with small areas of bronchiectasis.

The 6- to 11-month old F3 and F4 generation animals, with 9 to 15 rats in each group of the combined generations, showed remarkable improvement. There were no abscesses or areas of consolidation in the lungs of any of the animals. However, in the control and chlortetracycline groups, exudates were present in the nasal passages of 12 rats and in the middle ears of 15 rats. PPLO were isolated from the exudates of the nasal passages of 1 rat and from exudates of the middle ears of 5 in these two groups. No exudates were present in the nasal passages or in the middle ears of the rats fed the sulfamerazine.

In 10 mice inoculated with exudates from the control group of rats, 3 had exudates in the nasal passages and 3 had pneumonia. Of 10 mice inoculated with exudates from the chlortetracycline group, 5 had exudates in the nasal passages, and 3 had pneumonia. The 10 mice exposed to nasal passage and middle ear washings from the sulfamerazine group had no exudates in the nasal passages or middle ears and no gross or microscopic lesions in the lungs. Seven of these mice showed clumps of macrophages in some of the alveoli.

In the F5 generation, the 14 rats in the sulfamerazine group again showed no exudates or lung lesions, while exudates were seen and PPLO were cultured from the nasal passages of the control and chlortetracycline groups of animals.

Histopathological examinations of the lungs of mice that were inoculated with nasal and

middle ear washings and emulsions of lung tissue from the three groups of F5 generation rats revealed bronchial pneumonia in each group of mice except those inoculated with washings or tissues from the sulfamerazine group of rats. No gross or microscopic evidence of toxicity or deleterious effects on any of the organs or on reproduction were seen in any of the animals.

In this experiment, sulfamerazine given daily in the feed eliminated rhinitis, middle ear infection, and endemic pneumonia in the 3d, 4th, and 5th generations of rats. Giving the drug at a daily dose rate of 5 mg. in 20 gm. of ground rat feed may be a good, practical way to obtain a rat colony free of chronic respiratory disease.

Other Bacterial and Viral Diseases

Endemic pneumonia, frequent in mouse colonies, is a contagious disease producing high morbidity and mortality. Preliminary tests indicate that the infection may be treated by offering 1.0 mg. of chlortetracycline daily in drinking water.

Epidemic diarrheal disease of suckling mice is of major concern to mouse breeders, since losses from it are as high as 70 percent and the production of mice is markedly reduced. Research workers are often forced to discontinue tests because of outbreaks of infant diarrhea. The disease occurs in mice 2- to 15-days old; older mice and nursing females are immune.

The symptoms, epidemiology, and transmissibility of the disease were reported in 1947 (6), and intranuclear and cytoplasmic inclusion bodies in the superficial epithelial cells of the small intestines have been described (7). Kraft transmitted infant diarrhea in suckling CFW mice by feeding crude and filtered intestinal contents from infected mice and noted cage-to-cage infections which she attributed to airborne or fly transmission (8).

In 1957, we infected 3- to 4-day-old mice through 10 serial passages with oral and intranasal suspensions of intestinal filtrates from mice with infant diarrhea. Ten serial transmissions of the infant diarrhea virus were also made on Chang liver tissue culture media. Infected Chang liver culture fluid from the second passage of the virus produced diarrhea in

7- to 10-day-old mice exposed intranasally. No chemotherapeutic treatment or other preventive measures have been effective in controlling this disease.

Snuffles and mucoid enteritis cause considerable losses of rabbits each year. Snuffles is a highly contagious respiratory disease, reported to be caused by *Pasteurella leptiseptica* and *Haemophilus bronchisepticus*. However, we have been unable to reproduce this disease experimentally in susceptible young rabbits. Chemotherapeutic treatments have been unsuccessful in the treatment of this disease.

Mucoid enteritis, which affects rabbits 5- to 7-weeks old, is responsible for losses up to 70 percent in some colonies. Its cause is unknown, but Templeton (9) has attributed it to hereditary or nutritional factors. He reported that chlortetracycline and vitamin B₁₂ in feed reduced sickness and losses.

The disease most serious and injurious to guinea pigs is lymphadenitis, caused by streptococci type C. The guinea pig colonies of the Animal Production Section have been free of lymphadenitis since 1954. They were established and expanded from a small group of animals which were kept under strict methods of isolation and sanitation.

Salivary gland disease is a viral disease in guinea pigs recognized by the cytomegalic intranuclear inclusion bodies in the ductal epithelial cells of the submaxillary gland. We have been able to transmit this disease serially in young, pregnant guinea pigs and have produced death and abortion in the experimental animals. However, we have not been able to show that this disease occurring naturally is injurious or causes pregnancy toxemia.

Pregnancy toxemia is thought to be a viral disease of guinea pigs which is recognized by abortion during the latter part of the gestation period and death of the mother during abortion or a day or two after parturition. No treatment is known for it.

Diseases of unknown etiology occurring in laboratory animals are periarteritis in rats, calcium deficiency in guinea pigs, and amyloi-

dosis in hamsters. No methods of control or treatment for these diseases have been reported.

Neoplasms are frequently seen in aged mice, rats, and guinea pigs, but seem to be infrequent in rabbits and hamsters.

Conclusion

The external and internal parasites and the bacterial and viral diseases cause enormous losses of laboratory animals and markedly increase the cost of research. These losses from diseases can be reduced considerably and the number of disease-free animals available for use in forming animal colonies can be markedly increased by good animal husbandry practices and sanitation, and by the development of effective methods of treatment and control.

After sketching briefly the development of military preventive medicine in the U. S. Army, Dr. Whayne discusses the preventive medicine volumes of the official history of the U. S. Army Medical Department in World War II and points out their usefulness in civilian public health and preventive medicine.

The History of Preventive Medicine in World War II

TOM F. WHAYNE, M.D., Dr.P.H.

WHEN Sir William Osler, soon after the turn of the century, said that preventive medicine is the medicine of tomorrow, he was looking far ahead. He was to live through one world war, and when he died, the year after it ended, it was still regarded as the war to end all wars. He could not foresee the time, a quarter of a century later, when, in the stresses of a global war, all the knowledge of civilian experts in public health and preventive medicine would be pooled with that of medicomilitary experts to make history in these fields at home and in the far corners of the earth.

Modern advances in both military and civilian preventive medicine and public health grew out of the shocking morbidity and mortality of typhoid fever in the Spanish-American War and the challenge of yellow fever and malaria soon afterward. There was close cooperation in those days between Brig. Gen. George M. Sternberg and his group at the Army Medical School and the group on the Johns Hopkins Medical School faculty headed by William H. Welch. The cooperation was so close, in fact,

that it would be hard to separate the military and civilian contributions of those years. Fortunately, this is not necessary. There was glory enough for all. Fortunately, too, there were young men like Maj. Walter Reed, who were eager to accept the challenge of the times and to use the new tools, the most useful of which was, and still is, field investigation using epidemiological techniques.

Although preventive medicine still had far to go when World War I began, the developments which had already occurred and the functional organization of resources and personnel accounted for a brilliant record of achievement, seriously marred only by the devastating epidemic of influenza in the fall of 1918. Epidemiological techniques, field investigations, combined epidemiological-laboratory teams for the expeditious evaluation of disease outbreaks and a focal attack upon them, methods developed for the control of the environment—these were far-reaching developments which have solved many a medicomilitary and civilian problem since.

At the beginning of World War II, Brig. Gen. James Stephens Simmons, outstanding in a group of outstanding preventive medicine and public health specialists in the Office of the Army Surgeon General, was selected to plan,

Dr. Whayne, Colonel, MC, USA (Ret.), is now professor of preventive medicine and associate dean, School of Medicine, University of Pennsylvania, Philadelphia.

develop, and administer the Army program in these fields. He was an admirable choice. He had inherited the traditions of Sternberg and Reed. He had served under Gorgas. He was a recognized authority in epidemiology, the laboratory sciences, and tropical medicine. He had worked closely, in an aura of warm personal friendships, with civilian experts in his own and other fields.

General Simmons was one of the somewhat limited group who appreciated from the beginning the global nature of World War II. He built up a flexible, practical, and highly effective military organization. He had the foresight to plan a medical intelligence organization which provided essential, global information on health hazards and conditions. His greatest contribution, however, was the forging of civilian and military experts into a homogeneous, cordial, and productive working relationship. The stimulus thus provided for cooperative endeavors was among the most precious commodities to come out of the war. By their joint efforts, these groups solved medical problems in environments ranging from the Arctic to the tropical lands of Africa and the far islands of the Pacific. The Army Epidemiological Board and the United States of America Typhus Commission, whose published reports fill a 3-foot shelf, were General Simmons' concept.

History of World War II

Medical military history, in the formalized modern sense, began with the publication, only 2 years after the end of hostilities, of the story of the Crimean War. This history was written because Andrew Smith, director general of the British Army Medical Service, found himself, on assuming his task, with "a complete absence of all details of previous wars calculated to instruct," and he determined that no successor of his should ever again find himself in that situation. In spite of the wide differences in the circumstances of the two wars, these volumes on the Crimean War, as Surgeon Joseph J. Woodward said, "gave direction" to the efforts of the U. S. Army Medical Department in the Civil War. Brig. Gen. Frank W. Weed, editor in chief of the Medical Department history of World War I, wrote later that if there had

existed during the Civil War a dependable record of earlier wars in this country, epidemics might have been foreseen, even in those pre-epidemiology days, and diarrheas prevented.

The volumes that make up the series entitled "Medical Department, United States Army, in World War II" are part of a total series of about 125 (proposed) volumes dealing with all aspects of the war in all theaters in which it was fought. The Medical Department series will eventually consist of about 50 volumes. One volume, in the surgical series, was published in 1952. Since the fall of 1955, there also have been published, exclusive of the preventive medicine volumes, 1 (of 8 scheduled) administrative volume; 6 (of 15 scheduled) surgical volumes; and a dental volume and a volume on cold injury (in a series of 8 scheduled volumes on various other subjects). It is hoped that all the medical volumes can be completed by the end of 1961.

Preventive Medicine Volumes

When the preventive medicine series of this history was planned, General Simmons was selected as chairman of the advisory editorial board, a position which he filled brilliantly until his death in 1954. His work was then taken over by Brig. Gen. Stanhope Bayne-Jones (Ret.), who has served with equal wisdom and competence.

The advisory editorial board set up under General Simmons consists of men distinguished in the field of preventive medicine, all of whom were in service, in positions of responsibility, at home or overseas. They developed the outline for the history and selected the authors and reviewers for the various chapters. With great wisdom, they selected the authors from among men who had "been there," who understood administrative and other military problems as well as epidemiological and other preventive medicine problems, and who could relate both to the environment in which these problems arose.

Of the 8 volumes proposed in this series, 3 have already been published. One dealing with environmental hygiene and another with personal health measures and immunization were published in 1955. One of the three vol-

umes on communicable diseases was published in 1958; another will appear in 1959. The remaining volumes will cover the organization and operation of the program; malaria and other anthropod-borne diseases; civil health problems; and education, laboratories, and training.

The volume on environmental hygiene relates how sanitarians, entomologists, engineers, and physicians maintained standards of sanitation in areas of endemic disease and in the midst of destroyed water and waste disposal systems, or how they set up these systems in areas in which they had never existed. The subjects covered include food management, housing, water purification, waste disposal, insect control, rodent control, the research background of these programs, foreign quarantine, and preventive medicine in ports of embarkation and for persons in transit.

The story told in this book is impressive. Plague was not reported in U. S. Army personnel during the war. No plague-infecting rodent was recovered from a United States military vessel or aircraft. Only 13 cases of cholera were reported during the whole war, and only 102 cases of louseborne typhus, only 1 of which was fatal. There were no cases of yellow fever.

Subjects covered in the volume on personal health measures and immunization include the selection of manpower and the lessons learned from the physical and mental defects thus revealed, personal hygiene, clothing, malnutrition and deficiency diseases, preventive psychiatry, accidental trauma, and the Army immunization program. The tetanus program is typical of the success of many of these measures. Only 12 cases were recorded in the whole Army, and 6 of these were in personnel who had never been immunized.

During World War II, almost 33,000 deaths overseas were caused by nonbattle injuries. More realistically, nonbattle trauma was the cause of 1 in every 5 notifications of death sent to the family of a United States soldier. This is a problem which has existed since the Revolutionary War and which has increased in gravity as mechanization of the Armed Forces has increased. It is also, as a British military ophthalmologist forthrightly put it, augmented by "the stupidities of fools." As the

Availability of Volumes

Upon publication the preventive medicine volumes in the history of the Medical Department, United States Army, in World War II are placed on sale by the Superintendent of Documents, Government Printing Office, Washington 25, D. C. The following are now available:

Environmental Hygiene, vol. 2, 1955, 404 pp., \$3.50.

Personal Health Measures and Immunization, vol. 3, 1955, 394 pp., \$3.25.

Communicable Disease, vol. 4, 1958, 544 pp., \$5.50.

war ended, it was outstandingly demonstrated that there was need for military and civilian organizations in many fields to combine their efforts for the solution of what is a major public health as well as a major military problem.

The first of the volumes on communicable diseases to be published concerns diseases transmitted through the respiratory and alimentary tracts. It begins with an excellent chapter on modes of transmission and then discusses special diseases and disease groups.

Interesting comparisons can be made between the diseases discussed in this volume and those discussed in the World War I history. The slight discussion of amebiasis in the World War I history and the extended discussion in this volume, for instance, indicate not only the importance of this disease at this time but also the greatly increased knowledge concerning it.

Tuberculosis was a major problem in World War I, when X-ray techniques were crude by modern standards and screening was chiefly characterized by good intentions. Patients from World War I are still part of the population of Veterans Administration hospitals. In World War II, the efficient screening and case-finding methods which had been developed between the wars were put to good use. The Military Government Organization undertook the control of tuberculosis as one of its first functions during the period of occupation, rightly regarding the restoration of normal case-finding and reporting practices as quite as

important as the provision of beds for tuberculous patients. Research during the war also produced valuable information on two subjects. One was the inherent risk of small lesions whose activity is difficult to determine. The other was the causes of breakdown from tuberculosis, including the types of stress which lead to relapse and those which can be withstood without the breakdown of a latent lesion.

Historically, meningococcal meningitis has always been a disease of serious concern to workers in both civilian and military preventive medicine. Across the years, whatever progress has been made in prevention and treatment in one field has been quickly applied in the other. Both civilian and military experts worked on this disease in World War II. Sulfadiazine, used prophylactically, was reasonably effective in the military organization, but prevention in a heterogeneous and nonregimented civilian population was—and still is—impractical. Treatment, in spite of modern advances, is still far from satisfactory. The situation in World War II was improved over World War I. Although this disease ranked 76th in admissions to Army hospitals in the first world war, it was the 6th ranking cause of death because 40 percent of the cases were fatal. Civilian and military experts must continue to pool their efforts if the disease is to be controlled.

Use of Preventive Medicine Volumes

The volumes in the preventive medicine series are not a chronological record of events. Their primary objective is a searching evaluation of military preventive medicine in a global war. They tell the engrossing story of attempts to control diseases, modify environments, and maintain the health of military and civilian populations under wartime conditions in a conflict that covered the earth. Some diseases had never before been recognized. Every new environment offered new potential threats. The very water the troops drank and the rivers in which they bathed were hazards. As always happens, our knowledge of the natural history of disease and of human ecology in its broadest perspective was increased by these wartime experiences.

The principles and practices of preventive

medicine and public health had to be applied to young and healthy men in military service, and they also had to be applied to large civilian populations of all ages and races and of both sexes. In liberated and occupied countries, this was the responsibility of the Civil Affairs and Military Government Organization. The prevention of disease and the control of environmental factors were accomplished rapidly and efficiently because of military-civilian teamwork. The principles and practices of military preventive medicine and of civilian public health often overlap, but they are fundamentally the same, even when the local population and environment to which they must be applied are different.

Reviewers of the volumes of the preventive medicine series have shown great appreciation *of their objectives as well as of the methods by which these objectives have been attained.* Among the points they make are these:

1. As these books show, preventive medicine is a comprehensive discipline, which encompasses far more than environmental sanitation and the control of communicable diseases.

2. In these books, the source material is so distilled that the reader who could not possibly digest it in the mass need concern himself only with the essence. They are packed with factual data, including comprehensive and extremely useful statistical data. They also frankly confess errors.

3. These are very readable books. Says a British reviewer, "Our American cousins have good reason to be proud." Says an American reviewer, who was undoubtedly in service himself, these volumes are recommended to "those hopefully still vigorous spirits who might enjoy just reminiscing," a point which reviewers of other volumes in the series have also emphasized.

4. The material is applicable to many areas of civilian public health and preventive medicine. These volumes contain much for such specialists as the sanitary engineer and the sanitarian, the entomologist, the industrial hygienist and others in industrial practice, the veterinarian, the nutritionist, and the public health nurse. They should also be of interest and profit to the organizations, institutions, and agencies in which these specialists work,

including both official and voluntary health agencies, medical schools and schools of public health, research institutions, hospitals, medical departments of commercial firms and factories, and national and international health agencies outside the United States.

Practicing physicians today must have a broad understanding of all aspects of the prevention of disease and of the influence of the physical and social environment upon their patients. They too will find these books useful.

Finally, civil defense organizations require a specific knowledge of emergency health programs which are applicable upon a mass basis. The preventive medicine story of World War II as it is recorded in these volumes is the basis of much of the medicine of the future, in which medicomilitary and civilian cooperation will be necessary for the protection and maintenance of health under conditions which invite disease and trauma.

It takes more than the mere existence of a medical military history to make such a history useful. The value of the Civil War history was never fully realized because it was distributed on an individual basis, through members of the Congress. The distribution of the World War I medical history was considerably more logical, but it was scarcely publicized, and we paid dearly for the oversight in World War II, when the majority of medical officers were almost completely ignorant of what had been done in World War I both in their special fields and

in the general medicomilitary field. As I have helped to prepare the medical history of World War II, I have had many occasions, for comparative purposes, to refer to the World War I history, and, to my chagrin, I have often found in these volumes the plain and clear answers to many of the problems over which I and my associates struggled in World War II. It would pay all of us to remember another saying of Sir William Osler's, that by the historical method alone can many of the problems of medicine be approached most profitably.

Conclusions

Since the end of World War II, there has been a dramatic decline in the extent and severity of many diseases of public health and military significance. Malaria, for instance, by a continuation of the wartime lessons, is in a fair way to being tamed and even eradicated in most of the world within the near future. This is also true of other diseases. But the work is far from done, and those responsible for progress in preventive medicine and public health in civil life may profit greatly by studying the experiences of military men in World War II. In the volumes devoted to preventive medicine in the official history of the U. S. Army Medical Department are set forth methods, techniques, and basic philosophy as they are applicable to civilian public health and preventive medicine of today and even of tomorrow.

PHS Cancer Chemotherapy Project Matures

The Public Health Service's cancer chemotherapy program, mobilizing resources of hospitals, universities, research laboratories, industry, and government, has steadily expanded over the last 5 years with the following results:

- More than 40,000 compounds and other materials are being tested annually on more than a million mice to uncover chemicals with anticancer properties. About 70,000 materials have been screened.
- Between 400 and 600 materials a year are promising enough to be further analyzed with tests in mice and larger animals. Nine out of 10 materials are rejected as either ineffective or too toxic.
- About 40 materials a year are approved for clinical trials with human patients. Currently 70 are undergoing clinical trials.

Although incidence of poliomyelitis in this relatively isolated community of western Montana has been considerably lower than in more densely populated urban areas, the epidemiological characteristics of the disease have remained unchanged.

Naturally Occurring Poliomyelitis Antibody in Hamilton, Montana

ROBERT K. GERLOFF, M.A., CARL L. LARSON, M.D., and LILLIAN R. B. GLESNE

SEROLOGIC SURVEYS have been useful for epidemiological study of many diseases, detection of their occurrences in communities, and determination of the immune status of populations to such diseases. They have been especially applicable to studies of poliomyelitis, and, for this particular disease, have been greatly enhanced by the development of simplified, tissue-culture tests for neutralizing antibody. Among the more extensive poliomyelitis investigations in the United States is the one of Melnick and his associates (1) made in Charleston, S. C., and Phoenix, Ariz. Fox and his associates (2) have thoroughly studied three communities in Louisiana.

The survey reported here was conducted in a rural community in western Montana. Data portraying incidence of poliomyelitis antibody in this area emphasize particularly the relationship between age and prevalence of antibody, relationship between age and antibody titer, and intrafamilial spread of poliovirus.

General Procedure

The community studied was Hamilton, Mont., and its environs of approximately 24 square miles. Population of this area is about 5,500, of which 75 percent reside in the town itself. Mountainous terrain, practically without settle-

ment, extends 75 miles east, 100 miles south, and 125 miles west from the study area. U. S. Highway 93 passes through Hamilton in a north-south direction; a spur busline connects it with transcontinental transportation at Missoula, 50 miles north. In contrast to many densely populated Atlantic and Pacific coastal areas, this community is relatively isolated with respect to geographic setting and proximity to main commercial routes of travel.

Through cooperation of the four schools in the area, 1,034 blood samples were collected in February 1955 for serologic study. Most were from children in grades 1 through 12, but 138 were from adults and 50 were from preschool children. Specimens were obtained from 94 percent of the pupils in the three elementary schools and from 76 percent in the high school. Brief histories, including age and location of residence, were obtained from all participants. Presumably, none of them had received poliomyelitis vaccine, since commercial vaccine was

The authors are with the Rocky Mountain Laboratory, National Institute of Allergy and Infectious Diseases, Public Health Service, in Hamilton, Mont. Mr. Gerloff is a bacteriologist in the Serology-Pathology Section, Dr. Larson is director of the entire laboratory, and Miss Glesne is a research technician.

not yet available and experimental vaccine had not been tested in this area. Serums were classified according to age of the donor (table 1); age 6-7, for example, signified any age from 72 months through the day preceding the eighth birthday. Children less than 6 years old were grouped as preschool children, and persons 21 years or older were grouped as adults.

Laboratory Procedures

Serums were frozen at -24° C. until tested for poliomyelitis neutralizing antibody. A metabolic inhibition test, similar to one described by Salk and co-workers (3), was employed. All serums were tested in twofold dilutions, 1:8 through 1:1,024. Serums with 1:8 or higher titer were designated seropositive. Those with titer of 1:1,024 might have been positive also in higher dilutions, if such dilutions had been tested.

Age and Incidence

With a few exceptions, incidence of antibody to a specific type of poliovirus or to a combination of types gradually increased as age of the subjects increased (table 1). The greatest deviation from this trend occurred with respect to type 2 antibody, which was found in 48 percent of children aged 14-15, but in a considerably smaller percentage of children immediately older or younger.

There was no evidence that poliovirus either had recently entered the community or had been present several years before and then disappeared, leaving only older persons immune. In all age groups, type 2 antibody was more prevalent than type 3; in all except the 12-13 and 14-15 age groups, type 1 antibody was more prevalent than either type 2 or type 3. Among preschool children, 51 percent possessed one or more types of antibody, and the percentage gradually increased by age groups to 96 percent in adults. However, only 2 percent of preschool children, about 5 percent of high school students, and 20 percent of adults had all three types of antibody.

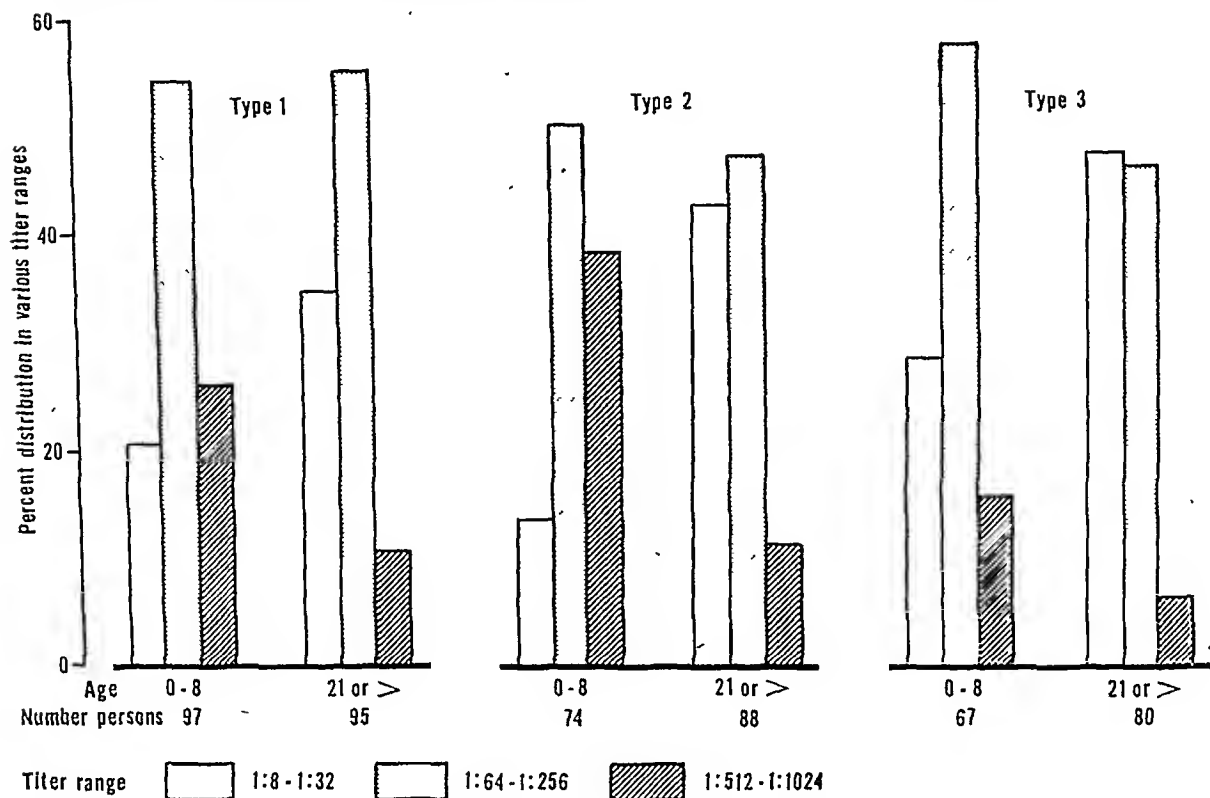

Age and Antibody Titer

Seropositive serums from the adults and from children through 8 years of age were compared on a basis of antibody titers to the three polioviruses. This age range of children was selected so that numbers of seropositive serums from them and from the adult group would be similar. Type 1 antibody occurred in 97 of the 276 children and in 95 of the 138 adults (see chart). Whereas 21 percent of the children and 35 percent of the adults had titers in the 1:8 to 1:32 range, 26 percent and 10 percent, respectively, had titers in the 1:512 to 1:1,024 range. Almost equal percentages had titers in the intermediate range of 1:64 to 1:256. Titers of antibody to the other polioviruses in the two age groups were similarly

Table 1. Distribution of poliomyelitis antibody in a population sample of 1,034 persons, Hamilton, Mont., by age group and poliovirus type

Age (years)	Number of persons in group	Percent seropositive against—				
		Type 1	Type 2	Type 3	All 3 types	One or more types
Under 6 (preschool)	50	31	14	12	2	51
6-7	141	33	28	24	3	61
8-9	152	39	33	28	6	67
10-11	155	37	36	34	7	68
12-13	157	37	37	33	7	70
14-15	130	44	48	35	4	80
16-17	111	53	38	36	6	85
21 or over (adults)	138	69	64	58	20	96

¹ With reference to the chart, 85 children in this group were 8 years old.

compared. However, because the same type or types of antibody did not occur in all persons, the composition of the groups included in the second and third analyses varied somewhat from that of the first.

Regardless of antibody type, more high titers were found in seropositive children than in seropositive adults. Differences were greatest in the type 2 analysis where only 11 percent of adults had titers in the high range as compared with 38 percent of children.

Intrafamilial Spread of Poliovirus

Serums from all children were grouped according to families (table 2). The extent to which poliovirus spreads within a family following its introduction by one or more carriers was studied by examining the degree of similarity in seroimmune patterns of children within each family. Each of the three types of poliovirus was considered a distinct disease entity, capable of invading a family independently of the other two types. Each

family, therefore, represented three family-type combinations. If, for example, the two children in a particular family both possessed type 1 antibody, neither had type 2, and only one had type 3, two of the combinations were said to be in agreement, but the third, in disagreement.

Of the 468 combinations represented by families with two children, 87 percent were in agreement and 13 percent were in disagreement. The analysis was continued to determine how many instances of disagreement could be explained on the basis of age difference. If the child possessing antibody was the older, perhaps he had acquired the antibody through natural infection before the younger child was born. Sixty-six percent of the instances of disagreement could be accounted for in this manner. As a final figure, 96 percent of the combinations represented by families with two children gave either perfect agreement or disagreement which might be explained by order of birth. Comparable final figures for families with 3 or 4 children were 90 and 79 percent,

not yet available and experimental vaccine had not been tested in this area. Serums were classified according to age of the donor (table 1); age 6-7, for example, signified any age from 72 months through the day preceding the eighth birthday. Children less than 6 years old were grouped as preschool children, and persons 21 years or older were grouped as adults.

Laboratory Procedures

Serums were frozen at -24° C. until tested for poliomyelitis neutralizing antibody. A metabolic inhibition test, similar to one described by Salk and co-workers (3), was employed. ¹ With reference to the chart, 85 children in this group were 8 years old.

poliovirus apparently are nonexistent in the community, as noted in an unpublished sewage study by C. L. Larson and his associates.

Because socioeconomic differences in the community are minimal and have little relationship to factors ordinarily considered of public health significance, the correlation between incidence of antibody and socioeconomic status was not thoroughly studied. The older north and newer south sections of the town of Hamilton were compared, however. In the south section, where the average family is generally considered to be somewhat above that of the north in income, cleanliness, and education, 41 percent of 217 children were without antibody to any type of poliovirus. In the north section, 20 percent of 192 children were in a similar condition.

Since high titers were found more frequently in children than in adults, they appear more likely to result from recent initial infections than from continued reexposure throughout life. Melnick and his associates (8) derived the same conclusion from complement fixation tests of human serums collected in Cairo, Egypt. Because poliomyelitis complement-fixing antibody, which is of relatively short duration in the blood, was confined almost entirely to childhood, re-infections in older persons were assumed to be rare. Le Bouvier (9) likewise concluded from data on Cairo residents that poliomyelitis antibody tends either to be absent from children or to exist in high titer, while in adults many medium or low titers are intermingled, due to gradual diminution of titers with age.

The data on seroimmune patterns of multiple children within the same families (table 2) augment other information (10,11) on the importance of intrafamilial contact in spread of poliovirus.

Since complement fixation tests were performed on serums from children of a rather narrow age span, results are of limited value. Ratios of percentage of children possessing neutralizing antibody to percentage possessing complement-fixing antibody were 6.3, 2.3, and 2.1 for types 1, 2, and 3 antibody, respectively. Because poliomyelitis complement-fixing antibody disappears much more rapidly than neu-

tralizing antibody, these data would indicate that types 2 and 3 poliovirus had invaded children 0-12 years old more recently than had type 1.

Summary

Incidence of poliomyelitis antibody resulting from natural infection in a relatively isolated rural community of western Montana was determined by tests of 1,034 serums collected from residents, mostly children, in and near the town of Hamilton. Neutralizing antibody to all three types of poliovirus was present, but in nearly all age groups type 1 antibody was the most prevalent and type 3 the least prevalent. Incidence of antibody generally increased with increasing age of the population, but spread of poliovirus has been much slower in this community than in densely populated areas. Only 5 percent of the high school pupils, aged 14-17, had been infected by all three types of virus. High antibody titers occurred more frequently in children than in adults. Multiple children in individual families were, in most instances, either all immune or all non-immune to a particular type of virus, a fact which portrays the importance of household contact in spread of poliovirus through a community.

respectively. Only 4 families with 5 children were available for study, but 92 percent of the combinations represented by them gave perfect agreement.

Complement Fixation Studies

Complement fixation tests on 225 serums, representing a sample of approximately 40 percent of the children in the age group 0-12, were performed by Dr. David B. Lackman of this laboratory. Unheated antigens were used throughout. The percentages of the group possessing types 1, 2, and 3 neutralizing antibody were, respectively, 44, 37, and 25, while those with complement-fixing antibody were 7, 16, and 12.

Discussion

The three principal conclusions from these data, namely, that prevalence of poliomyelitis antibody in people of this community is directly related to their age, that children generally have higher antibody titers than adults, and that intrafamilial contact rapidly disseminates poliovirus, agree with conclusions of other investigators who have studied entirely different communities, most of which have been urban. During the past 18 years, type 1 has apparently been the most common type of poliovirus in this community, type 3 has been the least common,

and type 2 has been intermediate. This relationship in prevalence of the three types also exists in other areas of Montana (4). The high incidence of type 2 antibody in the 14-15 year age group, as compared with older or younger children, probably reflects past invasion of one particular classroom by type 2 virus.

Rate of acquisition of poliomyelitis antibody with increasing age appears lower in this community than in many other parts of the United States and is definitely lower than that in many other parts of the world. However, differences in methods of testing serums, including variations in the lowest serum dilution tested, complicate direct comparison of results reported by different laboratories. In the current investigation, only 6 percent of children 16-17 years old possessed all three types of antibody. Identical results have been reported from Swiss children aged 18-19 (5). In contrast, 40 percent of 5-year-old children in urban areas of Gothenburg, Sweden (6), and 75 percent of children 3 to 4 years old and more than 90 percent of children aged 7-9 in families of low socioeconomic class in Peru and Colombia (7) possess all three types of antibody. Poliovirus apparently spreads in people of western Montana at a rate similar to that in the higher socioeconomic class of people in Charleston, S. C., but at a much slower rate than in this class of Phoenix, Ariz., or in the lower socioeconomic class of either city (1). Poliovirus also spreads much more slowly in this Montana community than in three urban and semirural communities of Louisiana (2).

Slow dissemination of poliovirus in this area is probably due to an interplay of many environmental factors. The community is well separated from others. Many children go to and from school in private buses, but there are no public conveyances. Since there are no private schools, all children attend the same public schools. Streets are wide, homes are relatively far apart, and most homes have ample space for the occupants. Nearly all homes have indoor sanitary facilities. Although many families have private wells for water supply and nearby septic tanks for sewage disposal, necessity for such utilities is not restricted to any particular socioeconomic class. During many months of the year, human carriers of

poliovirus apparently are nonexistent in the community, as noted in an unpublished sewage study by C. L. Larson and his associates.

Because socioeconomic differences in the community are minimal and have little relationship to factors ordinarily considered of public health significance, the correlation between incidence of antibody and socioeconomic status was not thoroughly studied. The older north and newer south sections of the town of Hamilton were compared, however. In the south section, where the average family is generally considered to be somewhat above that of the north in income, cleanliness, and education, 41 percent of 217 children were without antibody to any type of poliovirus. In the north section, 20 percent of 192 children were in a similar condition.

Since high titers were found more frequently in children than in adults, they appear more likely to result from recent initial infections than from continued reexposure throughout life. Melnick and his associates (8) derived the same conclusion from complement fixation tests of human serums collected in Cairo, Egypt. Because poliomyelitis complement-fixing antibody, which is of relatively short duration in the blood, was confined almost entirely to childhood, re-infections in older persons were assumed to be rare. Le Bouvier (9) likewise concluded from data on Cairo residents that poliomyelitis antibody tends either to be absent from children or to exist in high titer, while in adults many medium or low titers are intermingled, due to gradual diminution of titers with age.

The data on seroimmune patterns of multiple children within the same families (table 2) augment other information (10,11) on the importance of intrafamilial contact in spread of poliovirus.

Since complement fixation tests were performed on serums from children of a rather narrow age span, results are of limited value. Ratios of percentage of children possessing neutralizing antibody to percentage possessing complement-fixing antibody were 6.3, 2.3, and 2.1 for types 1, 2, and 3 antibody, respectively. Because poliomyelitis complement-fixing antibody disappears much more rapidly than neu-

tralizing antibody, these data would indicate that types 2 and 3 poliovirus had invaded children 0-12 years old more recently than had type 1.

New Simplified Germ-Free Laboratory

The possibility that germ-free animals may be used for experiment in small laboratories of health departments and universities may be sped by the outcome of field tests of a device which has been demonstrated successfully at the University of Michigan. The cabinet was designed by Dr. Richard Horton, now with the National Institute of Allergy and Infectious Diseases of the Public Health Service.

Similar units are being made available to several institutions for field trials, some to be tested by experienced investigators and others to be tested by men with no previous experience with germ-free techniques.

Although germ-free laboratories have been operated successfully at Notre Dame University, Walter Reed Army Medical Center, and the National Institutes of Health, the cabinet designed by Dr. Horton is intended to func-

tion on a relatively simple and economical scale.

The apparatus, a sealed box of glass and metal, is about the size of a frozen food cabinet. Investigators reach into the sterile area through sealed-in rubber gauntlets. A pressure compartment at one end sterilizes all food and equipment by steam before it enters the living quarters of the germ-free animals. All air introduced into the cabinet is heated to 750° F. and is then cooled before it passes into the chamber. Excess food and feces have remained in the box for months without odor or signs of decomposition.

Dr. Gerald Abrams, Michigan pathologist, who tested the machine with guinea pigs delivered into the cabinet by sterile cesarean section, believes the device is also virus proof, but he has not yet tested that hypothesis.

*Conference of Municipal Public Health Engineers
on air pollution control, October 6, 1958*

Responsibilities of Local Health Agencies for Air Pollution Control

ACUTE effects on health, resulting in death, attributable to gross air pollution exposures of masses of people have been recognized and reported. More recently studies have suggested subclinical effects which may develop into chronic and acute biological damage upon prolonged exposure to moderate amounts of air pollution. As society advances, conditions which impede attainment of the maximum of physical and mental well-being are considered detrimental to health. Thus, air pollution which interferes with food consumption, water intake, sleep, relaxation, and recreation or which creates physical or mental stress is recognized as impairing health. In the past few decades concern with air pollution has changed considerably from primarily problems of smoke and fly ash to problems involving toxic and noxious fumes, gases, and dusts as well.

While the exact nature of various interactions of air pollutants has yet to be determined precisely, public interest in air pollution continues to increase. Consequently, each year additional local health officers and public administrators must face these questions: Should an air pollution control program be started in this community? and, if so, What should be the role of the local health department? This statement will not attempt to answer these questions; rather it is intended to focus attention on factors to be considered.

Public health administrators will find it is easy to adhere to the general thesis that air pollution control is best accomplished at the lowest level of government capable of effective action. Because air pollution control involves localized as well as area problems basic

activities are required at the lowest level capable of supporting the program needed. In the absence of precise tolerance limits for aerial contamination, local citizens' opinions of relative values tend to set the standards for community acceptability. Such standards may frequently be qualitative rather than quantitative, and should consider not only health and well-being but also damage and deterioration to property, interference with use of homes, businesses, or recreational facilities, and hazard to air and ground transportation. Thus each area must define its own need for air pollution control and determine the extent to which it will support such activities. Evaluation of need for air pollution control is facilitated by an inventory of sources, supplemented by strategic sampling and a recognition of other factors peculiar to the community.

It is not the purpose of this statement to advance public health agencies as the only logical administrative units to direct air pollution control programs. However, health departments do possess many valuable resources and skills useful to such activities. Furthermore, public health officials must exercise more interest in air quality if they are to satisfy the total health needs of the people they serve. Therefore, this statement will attempt to outline in an objective way the contributions that public health has to offer air pollution control.

There are several possible roles for a local health agency. The health department may be assigned direct, primary, and sole responsibility for air pollution control. It may provide advisory, consultative, or staff services if another agency is directly responsible. In some circumstances, responsibility may be split

Committee Members

Members of the Committee on Air Pollution Control of the Conference of Municipal Public Health Engineers which formulated this statement were P. W. Purdoin, director, division of air pollution control and environmental sanitation, Department of Public Health, Philadelphia, chairman; Eric W. Mood, director, bureau of environmental sanitation, Department of Public Health, New Haven, Conn.; and Charles L. Senn, director, sanitation division, Los Angeles City Health Department.

Also members were John W. Lemon, administrator, Fulton County Health Department, Atlanta, Ga.; Charles M. Copley, Jr., deputy health commissioner, environmental sanitation services, St. Louis Health Division, St. Louis; Wilmer H. Schulze, assistant commissioner of health, sanitary section, Baltimore City Health Department; and Stanley B. Stolz, public health engineer, Department of Public Health, New Rochelle, N. Y.

between two departments, one primarily a smoke abatement unit and the other the health department with responsibility for controlling odors and gaseous emissions.

Split jurisdiction does not readily permit unified planning of a total program and provides an opportunity for some problems to fall between the two agencies with resulting neglect or duplication. This type of administrative arrangement is so awkward that it is not recommended and, consequently, will not be discussed further.

Factors in Assigning Responsibility

There are many bases for deciding which unit of government should be assigned responsibility for air pollution control. It is true that the best selection depends on the local situation, but this statement alone does not offer any guide to an objective administrator. There are several criteria which may be used to ascertain the feasibility and appropriateness of assigning responsibility to any unit.

Perhaps the most important factors are the degree of emphasis which the community desires to place on this activity and the extent it is willing to support air pollution control

through appropriation of funds. In the Los Angeles County Air Pollution Control District, where appropriations have ranged around \$4 million annually, or about 50 cents per capita, it was only reasonable to establish an independent agency with air pollution control as its sole objective. In areas where local stresses have not been so great, there have been advantages in utilizing the administrative structure and other resources of existing agencies.

Where there is a choice to be made between two or more agencies, an objective analysis should consider these factors:

- Adequate administrative direction.
- Capability of the unit to provide, or acquire, the necessary requisites for the service.
- Possession of a staff of trained personnel adaptable to air pollution control work.
- Willingness of the unit selected to give to the activity the emphasis desired by the public.
- Availability of laboratory facilities.
- Benefits accruing from coordination with related activities.
- Public attitude.

From the perspective of these factors, it is readily apparent that health agencies have a great deal to offer to an air pollution control program.

Most health departments have established divisions that are principally concerned with the elements of the environment that affect health—pure food and water, a safe and healthy home, work, and recreational environment, and sanitary waste disposal. The air supply naturally must be considered in association with these other environmental fundamentals vital to life.

Where air pollution control is a responsibility of the health agency, it has been found to be advantageous to the agency's other responsibilities. Sanitarians in their recommendations for the ventilation of food establishments consider the problem of cooking odors. Industrial hygiene proposals for protecting workers inside the plant are coordinated with air pollution control requirements to prevent the uncontrolled venting of noxious fumes, gases, and dusts to the atmosphere. Disposal of waste products, whether liquid, solid, or gas, can be considered from an overall point of view. Laboratories used for industrial hygiene and

other purposes can also serve the air pollution control activity.

Health departments are equipped with personnel and facilities for public education, a most important aspect of an air pollution control program. Also, they have physicians who are experienced in medical epidemiology and who can analyze the data available and establish the proper correlation between community health and air pollution. Not the least asset is the public health administrator's orientation to stress prevention.

These advantages are attested, according to a 1956 survey, by the fact that the health department was responsible for air pollution control more often than any other single type of agency (1). This is not to belittle the very fine work of units in other departments. In fact, where smoke abatement is the major concern, there may be logical reasons to locate the activity elsewhere than in the health department. However, as a total approach to air pollution control evolves, it seems to have a greater affinity to health agencies or independent units.

The health officer is cautioned that he should not rush into an air sanitation program if he is not prepared to follow through with a total program, one that will attack nuisance problems of smoke, dust, and offensive odors as well as those pollutants whose association with specific biological responses is more readily proved. He must be prepared to give budget support and emphasis to the program to the extent of public demand. And he should add to his staff the chemical and mechanical engineers and other personnel necessary to service competently the community's needs.

Services Provided by Control Unit

Since ability to give the service desired is one of the most important factors in deciding what duties to assign an agency, the services provided by an air pollution control unit should be reviewed.

One basic activity inherent in practically all programs dealing with the environment is the observation and investigation of conditions in the field. Complaints are frequently the initial cause for the action, and many communities are content to measure the effectiveness of a program by the absence of complaints. Complaints

rest upon such tenuous factors as emotional reactions, social standards, past history, and vested interest that their usefulness is of a limited nature. To be sure that the community maintains the quality of air desired requires continuing self-initiated observation and surveillance. This immediately creates a need for standards for evaluation. The general purpose of the community's air pollution control program and the conditions of pollution which the community will not tolerate should be stated in a basic law adopted by its legislative body. These premises are usually amplified by more detailed standards and regulations promulgated by a designated rule-making body. With written criteria of this type it is possible to make objective field evaluations and initiate needed corrective actions uniformly and fairly.

Sighting smoke and dust and smelling odors is basic to most programs in correcting the most offensive gross pollution. It will soon become apparent, however, that treatment after illness is not the way to run an air pollution control program. Prevention, as in any other public health program, is the keynote of air pollution control. The chief preventive tool utilized is the review and approval of plans for new installations and major alterations or modifications of existing heating and processing equipment and related control devices.

Approval of plans leads logically to performance testing after an installation is complete. Such testing is also applied to existing installations to determine the extent to which they comply with legal standards for controlling emissions. Testing of stack emissions may be done by the governmental agency itself or under its supervision by the company in question, or by a consultant to either the agency or company. Engineering surveys of sources of emission help to determine where such tests will be most helpful.

Consideration should be given to air pollution in community planning, development, and redevelopment. There should also be some activity directed toward determining what is happening to the community's air supply on an overall and long-range basis. This involves sampling the air for analysis and correlating sample data with meteorologic factors and other conditions.

Atmospheric sampling and stack testing require the availability of laboratory services. The larger health departments frequently have laboratories serving industrial hygiene and sanitary engineering activities which can be adapted for air analyses. Also, many smaller local units use facilities made available through the cooperation of State health departments and other agencies. In some instances laboratory service is obtained by contract with an educational institution or private facility.

Personnel

The need for personnel is more directly related to the character of the community and the emphasis and quantity of services desired than to population and area served.

If inspections and observations are made, various types of personnel can be trained to do the work. However, if instruction in appropriate fuel-firing methods for heating equipment is also to be given, then personnel with practical experience as stationary engineers are required. In persons who evaluate and give advice regarding problems of dust, fumes, and gases, and who review plans, appropriate mechanical and chemical engineering training and air pollution control experience are desired assets. Laboratory work and sampling require either chemists or chemical engineers. All the various services require clerical assistance.

It can readily be seen that the smallest health units can afford few of these services other than provision of local observation and inspection. If the unit is so fortunate as to have an engineer on its staff, it can undertake other services. Lacking one, it will have to rely on State assistance for technical and laboratory services.

To establish a semi-independent, full-time air pollution control service would seem to require a minimum of three persons, an engineer-director, a clerk, and a chemist. In some circumstances, some agencies might prefer an "operating engineer" type of inspector instead of a chemist. This decision might depend on the background of the engineer-director.

Such a service, under 1958 economic conditions, would require an annual budget of at least \$15,000 to \$20,000. This would mean an

expenditure of 15 to 20 cents per capita for a community of 100,000 population. Therefore, it is unlikely that very many communities of less than 100,000 population will want to establish semi-independent, full-time units. Larger units can seldom operate a program on less than 5 cents per capita, while 10 to 15 cents is more likely, and some spend from 30 to 50 cents per capita.

Even a unit with the minimum staff indicated will require some assistance from the State agency on more complex and unusual problems. It would probably be unwise for a health officer to assume responsibility for air pollution control without assurance of budget support for at least the minimum staff indicated, unless there is ample assistance in quality and quantity of personnel and facilities from the State agency for the necessary technical and analytical work.

Role of Local Health Department

Now that criteria for establishment and assignment of the air pollution control functions have been reviewed, as well as the services provided and staff required, it is possible to consider objectively a more precise definition of the role to be exercised by the local health agency. The health department either may be primarily responsible for the administration of the program, or it may serve in an advisory and consultative capacity.

It appears self-evident that the health agency must be considered and consulted, even in situations where it does not have the primary responsibility. The health department has a previously established concern with the ventilation of food establishments, maintenance of acceptable atmosphere in industrial and other work areas, and standards for the storage and disposal of wastes, particularly contaminated wastes such as those of clinics and hospitals.

The impact of air pollution control regulations on these matters and the impact of health department activities on air pollution should be considered by both the health department and the air pollution control agency. Joint consideration of proposed changes in standards appears essential. A mechanism for joint review of plans under which one agency would

not grant approval without consent of the other is desirable.

In some circumstances, the health department may have established laboratory facilities for industrial hygiene and sanitary engineering. Such facilities could be used by the air pollution control unit to avoid the necessity of building a new laboratory. The health department then would serve as a contractor of services as well as consultant.

Where prime responsibility for air sanitation is vested in the health department, the health officer must provide the vigorous leadership necessary to combat air pollution successfully and to foster the social and economic development of the community. The health agency must also provide in a competent and efficient manner the various services such as answering complaints, observing air pollution episodes, making engineering surveys of air pollution sources, testing stack discharges, sampling and analyzing the air over the community, reviewing plans, and issuing permits.

Also, the health department must assume responsibility for coordination of air pollution control efforts with other governmental operations, such as, city planning, zoning, urban development and redevelopment, and traffic. The health department cannot ignore air pollution nuisances and concentrate only on health hazards; it must provide a total community program to satisfy all needs.

In many instances, air pollution problems transcend the boundaries of a single political jurisdiction. This is an old problem for public health administrators. Cooperation is necessary to develop the appropriate regional administrative machinery to handle such problems effectively.

In a few areas, special districts or authorities have been established. However, such single purpose districts help to confound the problem of government in metropolitan areas. Also, many political scientists object to the removal of control of the government by the people that is inherent in many such systems. It would seem that the experience of public health adminis-

trators could be directed to this problem to evolve a more satisfactory solution.

Summary

There appear to be a few basic points that public health administrators and others may consider with respect to the establishment and organization of air pollution control activities:

1. Local conditions and emphasis desired will help determine the best organizational setting for any air pollution control activities.

2. Observed and suggested health effects of air pollution will cause increased investigation by health authorities.

3. Because of its natural interest in the total health of the community, the health agency must be concerned with air pollution.

4. *The health department may be involved in air pollution control in 1 of 2 ways: either as a consultant and adviser or as a primary administrator.*

5. The health department's concern with the total environment, of which air is a vital component, provides many advantages favoring the health department as the primary administrator of the air pollution control program.

6. The health officer should avoid commitments to air pollution control when he is unwilling or unable to provide the leadership, budget, and emphasis required by local conditions.

7. Where public health administrators are interested in air pollution control, the health department has much to offer in the way of experienced community leadership, efficiency through coordination with other activities, adaptable personnel with parallel training and experience, and laboratory facilities. In such a setting, a program may be developed that will protect the public health and foster the economic and social development of the community.

In some circumstances, some agencies might prefer an "operating engineer" type of inspector instead of a chemist. This decision might depend on the background of the engineer-director.

Such a service, under 1958 economic conditions, would require an annual budget of at least \$15,000 to \$20,000. This would mean an

expenditure of 15 to 20 cents per capita for a community of 100,000 population. Therefore, it is unlikely that very many communities of less than 100,000 population will want to establish semi-independent, full-time units. Larger units can seldom operate a program on less than 5 cents per capita, while 10 to 15 cents is more likely, and some spend from 30 to 50 cents per capita.

Even a unit with the minimum staff indicated will require some assistance from the State agency on more complex and unusual problems. It would probably be unwise for a health officer to assume responsibility for air pollution control without assurance of budget support for at least the minimum staff indicated, unless there is ample assistance in quality and quantity of personnel and facilities from the State agency for the necessary technical and analytical work.

Role of Local Health Department

Now that criteria for establishment and assignment of the air pollution control functions have been reviewed, as well as the services provided and staff required, it is possible to consider objectively a more precise definition of the role to be exercised by the local health agency. The health department either may be primarily responsible for the administration of the program, or it may serve in an advisory and consultative capacity.

It appears self-evident that the health agency must be considered and consulted, even in situations where it does not have the primary responsibility. The health department has a previously established concern with the ventilation of food establishments, maintenance of acceptable atmosphere in industrial and other work areas, and standards for the storage and disposal of wastes, particularly contaminated wastes such as those of clinics and hospitals.

The impact of air pollution control regulations on these matters and the impact of health department activities on air pollution should be considered by both the health department and the air pollution control agency. Joint consideration of proposed changes in standards appears essential. A mechanism for joint review of plans under which one agency would

This material is supported by 39 tables and 12 graphs. Explanatory text includes appendixes containing technical notes on methods and definitions of terms.

Air Pollution Measurements of the National Air Sampling Network. Analyses of suspended particulates, 1953-1957. *PHS Publication No. 637; 1958; 260 pages; \$2.*

Air quality data from urban, suburban, and nonurban areas in the United States are reported. The text describes the analytical techniques applied to samples, and monthly and frequency distribution tables are presented for individual pollutants.

These data should be useful in determining correlations and trends in the nature, extent, causes, and effects of air pollution and in establishing the health significance of various pollutant levels.

Pneumoconiosis in Diatomite Mining and Processing. *PHS Publication No. 601; 1958; 96 pages; 55 cents.*

Results of an epidemiological study of diatomaceous earth pneumoconiosis in five diatomite plants in California, Nevada, and Oregon are described.

The report includes a review of the literature, a detailed description of diatoms and the diatomite-processing industry, discussion of the environmental and medical studies conducted, and specific recommendations for dust control, labeling, and a medical program.

The study was made by the Public Health Service in cooperation with the State health departments concerned.

A Manual for Metabolic Balance Studies. *PHS Publication No. 607; 1958; 31 pages; 20 cents.*

This manual presents basic information needed for conducting metabolic balance studies and describes methods used by the Arthritis and Metabolic Diseases Nursing Service of the Clinical Center, National Institutes of Health, Public Health Service.

In addition, there are chapters on the team concept for metabolic balance studies, the metabolic research diet, and orienting the patient.

Librally illustrated, the manual is designed to aid researchers in nutrition, mineral and electrolyte metabolism, and cancer.

Homemaker Service. *Children's Bureau Folder No. 46; 1958; 36 pages; 15 cents.*

Plausible examples of family crises depict the philosophy and operation of the homemaker service. This booklet tells who may need the service, under what circumstances it may be used, and how it may be financed. Establishing a homemaker service and its value to the community are also discussed.

The Water Pollution Control Program of the U. S. Public Health Service, 1957-1958. *PHS Publication No. 631; 1958; 26 pages; 25 cents.*

After recounting the changing water pollution problems, this brochure describes the program for their control.

The evolution of the program is outlined in sections on legislative history and congressional policy. Construction of sewage treatment plants, interstate enforcement activities, research, and basic data analysis are reported in nontechnical language.

Directed to the individual citizen, the last section summarizes the benefits, goals, and costs of the program.

Child-Caring Institutions. Their new role in community development of services. *Children's Bureau Publication No. 368; 1958; by Martin Gula; 27 pages; 15 cents.*

New patterns in community services and new demands on child-care institutions are discussed in relation to the dynamics of the individual community and changing conditions during the past 50 years.

Against this background, three levels of quality of establishments for the care of children are evolved,

and 20 ways to measure the effectiveness of these institutions are listed.

The booklet stresses the importance of close working relationships between organizations for children and the community. It should be useful to board and professional staff members of social agencies, community planning groups, legislators, and judges.

Where to Write for Birth and Death Records. *PHS Publication No. 630A; 1958; 10 pages; 15 cents.*

Where to Write for Marriage Records. *PHS Publication No. 630B; 1958; 8 pages; 5 cents.*

Where to Write for Divorce Records. *PHS Publication No. 630C; 1958; 8 pages; 10 cents.*

Information for getting records on births and deaths, marriages, and divorces from States, Territories, and other American governmental agencies is supplied. In addition, the first-named publication tells how to obtain records pertaining to births and deaths occurring in selected foreign countries.

Multiple Sclerosis. Hope through research. *PHS Publication No. 621 (Health Information Series No. 92); 1958; leaflet; single copies, 5 cents, \$3 per 100.* Describes symptoms of multiple sclerosis. Reviews theories on causes. Discusses research advances in diagnosis and possible treatment.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared with Federal support.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Office of Information, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

publications

Report of National Conference on Nursing Homes and Homes for the Aged, 1958. *PHS Publication No. 625; 85 pages; 55 cents.*

Complete proceedings of the first National Conference on Nursing Homes and Homes for the Aged held in Washington in February 1958 are presented. Principal addresses, background information, 103 recommendations adopted by the conference, and a synthesis of the discussions which led to each recommendation are included.

Recommendations and related discussions are grouped according to the eight sections in which they were evolved: role of nursing homes and homes for the aged (general policy questions); medical, nursing, and other selected professional services; nutrition and food service; social and related services; environmental health and safety; regulatory agency problems; financing of facilities and services (including design, construction, and equipment facilities); and administration.

Milestones in Venereal Disease Control. Highlights of a half-century. *PHS Publication No. 515; revised 1958; 12 pages; 10 cents.*

Brought up to date to include the newest techniques of serodiagnosis of syphilis, this easy-to-refer-to chronology is a modern history of venereal disease control. It will be useful to teachers, health and social workers, speakers, writers, and others needing ready reference to facts about the progress of venereal disease diagnosis and treatment.

Sources of Morbidity Data, Listing Number 6, 1958. *PHS Publication No. 628; 1958; 83 pages.*

Descriptions of 110 previously unreported projects in the files of the Clearinghouse on Current Morbidity Statistics Projects are grouped according to major type or types of disease, injury, or impairment with which they deal.

There are three indexes: the projects by type of data collection, the organizations chiefly responsible for the research, and the principal investigators. Also included is a section of supplementary notes representing a systematic followup on unfinished projects in the previous five listings.

The number of bound copies for distribution to other than actual and potential contributors is limited. Tearsheets for the projects are on file, however, for persons who inquire about studies of a particular type.

Immunization Information for International Travel. *PHS Publication No. 384; revised 1958; 71 pages; single copies, 30 cents, \$22.50 per 100.*

Immunization requirements for persons entering the United States (including Americans returning from abroad), requirements and recommendations for immunization in 200 other countries, and a list of yellow fever vaccination centers are presented. Information on bringing pets into the United States is in a special section.

Designed primarily for travelers going abroad, health departments, and physicians, this booklet supersedes the 1956 edition and 1957 supplement.

Municipal Sewage Treatment Needs. *PHS Publication No. 619; 1958; by John R. Thoman and Kenneth H. Jenkins; 16 pages; 15 cents.*

Data from the 1957 Inventory of Municipal and Industrial Wastes Facilities show needs for sewage treatment plants. These needs are grouped into six categories including new and replacement plants and additions to existing facilities. Reported data and applicable percentages for the various categories are arranged by States, community population groups, and major drainage basins. Tables show needs for various degrees of treatment as well

as for different types of plants within the primary and secondary groups.

This booklet is intended to be used in conjunction with Statistical Summary of Sewage Works in the United States, PHS Publication No. 609.

Source Materials on Water Pollution Control. *PHS Publication No. 243 (Public Health Bibliography Series No. 22); revised 1958; 24 pages.*

Current references, technical and nontechnical, are grouped under the headings: community action, financing and economic factors, laws and regulations, industrial wastes, domestic wastes, basic data and standards, research, biological aspects of water pollution, water supply, and films. In addition to about 100 PHS publications or reprints, references which may be consulted in libraries or purchased from the sources noted are listed.

Highlights of Progress in Research on Cancer. *PHS Publication No. 623; 1958; 51 pages; 25 cents.*

Research findings reported during 1957 by staff scientists and grantees of the National Cancer Institute, Public Health Service, are summarized to represent selected accomplishments in the study of cancer and to reflect current attitudes toward the more promising avenues of cancer research. The material ranges from basic laboratory studies and statistical analyses of the epidemiology of cancer to clinical research.

Summaries are organized under four broad headings: causation, characteristics, diagnosis, and treatment of cancer.

Health Statistics From the U. S. National Health Survey. Selected survey topics, United States, July 1957-June 1958. *PHS Publication No. 584-B5; 1958; 49 pages; 40 cents.*

Data collected from a continuous nationwide household-interview survey are the bases for this annual summary on disability, acute conditions, chronic conditions, persons injured, physician visits, and dental visits. Included are population estimates for use in rate computation in conjunction with the basic data.

Profile of American Families, 1940-57

WILLIAM F. PRATT

DESPITE the dire warnings we frequently hear concerning the deterioration of the American family, family life is more popular today than at any other time since the turn of the century. But marked changes are occurring in the patterns of family life, many of which have proceeded more rapidly since World War II. Change almost invariably creates tension, especially when it involves the modification of deeply rooted traditions or expectations. Many current social ills have been causally attributed to contemporary family life. If this is so, a basic understanding of changes in family life is indispensable to understanding these social problems.

The number of families in the United States has increased. More than three-fourths of the decline in the proportion of the population "never married" since 1890 occurred between 1940 and 1957 (fig. 1). In this period the proportion of men currently married increased from 59.7 to 67.3 percent, and of women from 59.5 to 66.4 percent (1*a*, 2*a*). The number of families increased 35.1 percent between 1940 and 1957 (2*b*). Four basic factors have contributed to this increase in families:

1. More couples survive to celebrate their golden wedding anniversary. Glick has estimated that median ages to which husbands and wives survive jointly increased 0.5 year between 1940 and 1950 (1*b*). The improvements in life

expectation since 1950 have undoubtedly extended this gain in the duration of marriage.

2. The proportion of remarried persons has increased. Although this trend started before 1940, the proportion of remarried women among those 15-44 years of age, with husband present, increased 4 percent between 1940 and 1950 (from 9 percent to 13 percent), or more than in the preceding 30 years (1*c*). The increasing proportion of remarried persons can be ascribed principally to the remarriages of divorced persons. In the years 1950 to 1956, there were 3 to 4 widowed brides and grooms to every 10 divorced brides and grooms (3*a*).

3. The greatest factor in the increased proportions of currently married persons, quite obviously, is the decline in the proportion remaining single. The proportion single of the population 14 years of age and older declined more than 6 percent between 1940 and 1957, 34.8 to 28.1 percent for men and 27.6 to 21.6 for women (1*a*, 2*a*). This decline was observed in each age group in 1955 compared with 1940 (1*d*). Between 1940 and 1955, the median age at first marriage dropped 1.6 years for men, or almost as much as in the preceding half century, while for women the median age dropped 1.3 years, or about twice as much as in the preceding half century (1*e*). Two social trends would seem to be particularly significant in the recent decline in the age of first marriage, especially in the oldest 25 percent. College enrollment of married students increased with the advent of the GI bill and the veteran-student. As recently as 1955, many colleges still reported increased enrollment of married students. The increased opportunities for, and acceptance of, married women in the labor force may well have paralleled the GI bill as a factor facilitating

Mr. Pratt is an analytical statistician in the Marriage and Divorce Analysis Section, National Office of Vital Statistics. This report was prepared originally for the American Social Hygiene Association for use in connection with the Conference of Executives of National Organizations in New York City, October 20-21, 1958.

ROCKY MOUNTAIN SPOTTED FEVER: VACCINATION OF MONKEYS AND MAN

By R. R. SPENCER, Surgeon, and R. R. PARKER, Special Expert, United States Public Health Service

In a previous publication¹ we have shown that guinea pigs may be successfully vaccinated against Rocky Mountain spotted fever by injections of phenolized emulsions of tick virus. Data are now submitted which (1) prove that this vaccine will also protect monkeys and (2) suggest that it will confer immunity upon man.

PREPARATION OF THE VACCINE

The production of a potent vaccine from tick emulsions is dependent upon a high concentration of virus in the ticks from which it is prepared. By the injection of decreasing amounts of emulsions of infected tick viscera into guinea pigs, the minimal infectious dose of any given emulsion may be approximately determined. After many such titrations, employing fed and unfed infected ticks (*D. andersoni*) at all stages of the life cycle, it has been found that the highest concentrations of spotted fever virus occur two to four days after the beginning of the adult feeding.²

Such ticks, usually in lots of 100, are permitted to feed three days on guinea pigs, then at once eviscerated one by one and ground in a mortar for 10 or 15 minutes with sterile sand and a few cubic centimeters of salt solution. By this procedure the internal organs

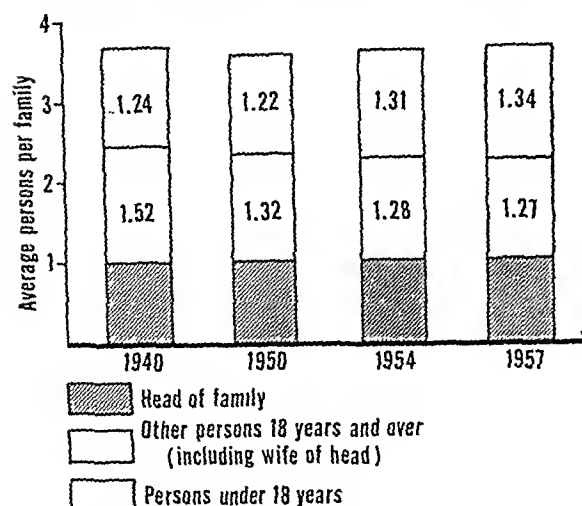

¹ Spencer, R. R., and Parker, R. R.: Rocky Mountain Spotted Fever: Experimental Studies on Tick Virus. Pub. Health Rept., Nov. 2, 1924. (Reprint No. 976)

² Rearing of infected ticks for the preparation of the vaccine.—The rearing of adult ticks from which the virus is obtained is a tedious process. (Potent virus can not be obtained from the tick in the nymphal stage.) Virus ingested by larvae does not increase appreciably in amount or virulence in nymphs, that any increase in amount or virulence is often greater than in the nymphs. It is then reared to adults; for it is necessary to begin operation with a large number of ticks, and only a few are selected for use.

October 9, 1925, pp. 2159-2167

Dr. R. R. Spencer and Dr. R. R. Parker found that a vaccine produced from tick emulsion immunized monkeys and perhaps man against Rocky Mountain spotted fever. In earlier studies, they demonstrated that this vaccine immunized guinea pigs (Public Health Reports 38: 333-339, Feb. 23, 1923, and 39: 3027-3040, Nov. 28, 1924).

Figure 2. Average family size and family members, by type, 1940, 1950, 1954, 1957.

SOURCE: References 1f and 2d.

result of the changing composition of families (fig. 2). Between 1940 and 1950, the average number of family members under 18 years of age decreased as a result of low birth rates in the 1930's. Between 1950 and 1954, the rising fertility of the late 1940's and early 1950's brought a substantial increase in the average number of family members under 18 years old (1f,2d). This trend continued to 1957 when there were 1.34 persons under 18 compared with 1.17 in 1950. However, throughout the period 1940-57, the average number of persons over 18 years of age fell from 2.52 to 2.27 (2e).

Changes in the household and family situation of persons over 65 years of age have been small, but in the direction of increasing isolation from kinsfolk. Between 1950 and 1957, the proportion of persons over 65 who were classified as unrelated individuals or inmates of institutions increased from 23.5 percent to 24.8 percent, or by 3,645,000 people. Among those 75 years of age and older, in the same period, the proportion classified as unrelated or as inmates of institutions rose from 27.8 to 30.2 percent, which was due to the increase in unrelated individuals.

Between 1950 and 1957, the proportion of persons over 65 years of age who were family members, but not the head of the family or the wife of the head (that is, dependent elders usually), declined from 21.2 to 18.1 percent.

In the same period, the proportion who were heads or wives of heads of husband-wife families increased from 44.4 to 47.2 percent (4,2f). The majority of these latter families (70.8 percent in 1953) were elderly couples with no other adult family members (1g). Also, most of these husband-wife families owned their own homes. The median income in 1949, however, was less than half, \$1,129, that for all husband-wife families, \$2,803 (1h).

Socioeconomic Conditions

The social and economic conditions of families have generally improved throughout the period 1940-57. The educational achievement of husbands in husband-wife families has increased from an average of 8.0 years in 1940 to 10.8 years in 1957. The educational improvement was greater for younger than for older husbands (1i,2g). Improvements in housing are reflected in less "doubling-up" of the generations. From 1947, when 8.7 percent of married couples were without their own household, the percentage dropped to 3.2 in 1957 (1j,2h).

Although money income alone is only a fair indicator of an increase in real wealth or buying power, the trend in family income, which has increased every year except 1949 and 1954 (from a median of \$2,533 in 1944 to \$4,971 in 1957), undoubtedly represents a real gain in the economic conditions of families (5a,b).

The improved social and economic conditions of families are associated with the increasing number of families with more than one earner, and especially with the increase of women in the labor force. Between 1948 and 1956, the number of families with more than one earner increased from 41 to 46 percent among non-farm families and 37 to 42 percent among farm families (5c).

Despite the increasing number of dependent children in families, the participation of married women in the labor force has increased. Among married women living with their husbands, 14.7 percent were in the labor force in 1940, and 29.6 percent in 1957. The increased participation was largest for married women over 35 years of age, which rose from 20.1 percent in 1947 to 30.0 percent in 1956; the largest proportional contribution to this

earlier marriage since the war. These trends may be regarded as part of the generally favorable economic conditions since World War II which have facilitated marriage.

4. Better economic conditions have also contributed to the increase of families by decreasing the "doubling-up" in households. At least 14 percent of the increase in families between 1950 and 1957 was due to the decrease in sub-families which would have otherwise lived with relatives (2*b*).

Fertility Rates

Parents today apparently want, or can afford, to care for more children. In 1956, the fertility rate reached 120.8 infants born alive per 1,000 women 15-44 years of age, which is in sharp contrast to the 1940 rate of 79.9 and is in excess of the 1947 rate of 113.3, the year of the "baby boom." Most important for trends in family size is that the increase in fertility rates in recent years has been due to increasing rates of third and higher order births, which have continued to rise since 1950 (3*b*). Between 1950

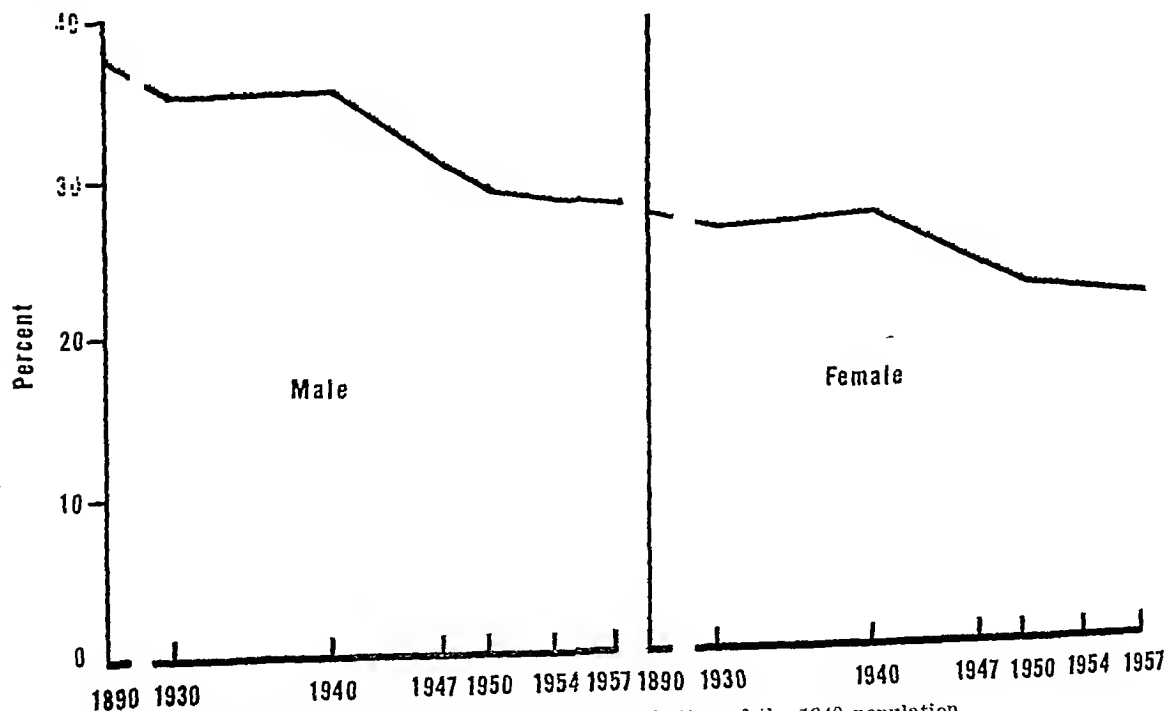

and 1957, all age groups of women 15-44 years of age who were ever married showed a marked increase in the number of children born to them. Moreover, while women with increasing education have fewer children, the proportional gains in fertility between 1950 and 1957 were greater as the level of education increased, excluding those with less than 8 years of schooling and with 4 or more years of college. Also, the proportional increase in fertility in the last 7 years was greater among women aged 15-44 in the labor force than among those not in the labor force (2*c*).

Family Composition

Despite the marked increase in fertility and children born, the average size of families has increased but little and only in the last few years. Average family size, which had decreased to 3.76 persons in 1940, decreased further to 3.53 persons in 1953. By 1957, the average size of families rose to 3.61, although this is still below the level for 1947 (1*f*, 2*d*).

The decline in family size up to 1953 is the

Figure 1. Percentage of persons never married, 14 years old and older, by sex, 1890-1957.

NOTE: Standardized for age; based on the age distribution of the 1940 population.
SOURCE: References 1a and 2a.

are rates of separation and widowhood. Divorce rates are lowest for women with 4 or more years of college, and highest for women with 1 to 3 years of high school. The rates of separation for women vary inversely with education (17). In recent years, the proportion of divorces affecting children and the median number of children per divorce involving children have increased (3g).

Illegitimacy is an increasing problem in family life. Between 1940 and 1956, the illegitimacy rate rose from 7.1 per 1,000 unmarried women 15-44 years of age to 20.2. The ratio of illegitimate births per 1,000 live births increased from 17.5 to 19.0 for white persons and 179.6 to 204.0 for nonwhite persons between 1950 and 1956 (9,10). In one study, premarital pregnancy was found to be associated with divorce and with young age at marriage (11).

Basic Problems

While many of the trends in American family life, especially since World War II, may be regarded as encouraging, sight must not be lost of the fact that many social problems thought to be closely related to family life have been increasing. Among these we may list juvenile delinquency, mental illness, illegitimacy, and living conditions and productive opportunities for our elder citizens.

In addition, with the improvement of public health methods in combating the great killers of yesterday, our attention must turn more and more to the prevention and control of chronic disease that saps the will and the physical energy of so many, especially in later years.

A basic step in understanding these problems and effecting preventive techniques lies in a more detailed study of the family as the unit of social, mental, and physical health. Among the research needs concerning the family, mention should be made of at least the following:

1. A statistically useful definition of the family for health and welfare purposes, including all relevant persons in and out of the household unit.

2. Nationwide coverage of marriage and divorce statistics, based on the centralized registration of marriages and divorces in all of the States. Data broadly similar to those obtained

for divorces should be obtained for families broken by death and separation.

3. More intensive study of differential mortality by marital status, age, sex, and race to locate the social and psychological correlates of mortality differences.

4. Intensive studies of health conditions and practices in the family unit as a whole, and of the functions of the family in rehabilitation and in preventing and treating illness.

growth was among women 45 to 64 years of age (6a,b). In 1955, husband-wife families with the wife in the labor force had a median income of \$5,622, compared with \$4,326 for families in which the wife did not work (5d). The thought is suggested from these and similar data that the erstwhile productive functions of the family unit may be returning in a new institutional form.

From the point of view of family growth, children seem to be less a barrier to the employment of the mother than formerly. The percentage increase between 1950 and 1957 in children born per 1,000 women 15-44 years old who were ever married was 13 percent greater among women who worked, a 30.7 percent increase, than among those not in the labor force, a 17.9 percent increase (2i).

This increase results in part from the greater increase of married women over 35 years old in the labor force, that is, women who have completed or nearly completed their childbearing. The proportion of married women in the labor force decreases with duration of marriage through the first few years, indicating that women leave the labor force during the early years of childbearing (7). Women with children under 6 years of age have a lower proportion in the labor force at all ages than women without children under 6, but the proportion increases among these women as age increases (6c). As the children enter school, mothers tend to return to work, as indicated by the much greater participation of women with children 6 to 17 years of age but none under 6 years old.

A current deficiency in statistics on the family is the lack of data on total family health, but certain indexes from vital statistics data reflect improvements in the health of family members. Between 1940 and 1956, the improvement in life expectancy at birth rose from 62.8 to 67.3 years for white males, and from 67.3 to 73.7 for white females. Although the improvement in life expectancy was greater for nonwhite males and females than for white persons in this period, a marked disparity remains (3c). Infant mortality provides another index, declining from a rate of 47.0 per 1,000 live births in 1940 to 26.0 in 1956 (8a,3d). Maternal mortality offers a similar picture of

marked gains in health for the family: a rate of 37.6 per 10,000 live births in 1940 dropped to 4.1 in 1956 (8b,3e).

Family Stability

The increasing proportion of remarried persons, mentioned earlier, and the increasing proportion of divorced persons suggest a growing problem of family instability. Actually, on the basis of available data, it is extremely difficult to assess the trend in family stability. The percentage of men currently divorced rose from 1.2 in 1940 to 1.8 in 1954; for women it rose from 1.6 to 2.2 in the same period. Between 1954 and 1957, the change in the percentage of persons currently divorced was negligible (1a,2a). The trend in the divorce rate per 1,000 women 15 years old and older through this period gives a different impression. From its highest point of 17.8 per 1,000 married women 15 and over in 1946, the divorce rate declined to 9.4 in 1956 (3f). Divorce trends alone can be misleading in assessing trends in family instability, since they do not reflect the total population of families broken by separation and desertion, from which the majority of divorcees arise. Much more detailed study, based on reliable nationwide statistics of family formation and dissolution, is needed before conclusive analyses can be presented.

Divorce has increased in relation to death as a type of family dissolution. While the proportion of currently divorced persons rose between 1940 and 1954, the proportion of currently widowed persons declined in the same period (1a). Comparisons of the trends in currently divorced and currently widowed understate the relative increase of divorces, since proportionately more people who were ever divorced are likely to be among the remarried at a given time than persons who were ever widowed. Most important is the fact that divorce, by and large, affects families relatively early in marriage, while death affects them much later.

Marriages of young persons (women less than 21 years of age) are less likely to be permanent than marriages of somewhat older persons (1k). Divorce rates are considerably higher for nonwhite than for white women, as

Collection of Data on Accidental Injuries

PHILIP S. LAWRENCE, Sc.D.

CONSIDERING that accidental injury is the major cause of death in the United States for the ages 1 to 35 years, there is an obvious need to collect and evaluate data about accidents by methods which may lead to plans for accident reduction.

The U.S. National Health Survey, authorized by Congress in 1957, specifically instructs the Public Health Service to evaluate the methods of gathering data and to facilitate the development of similar data by others, so as to speed the day when the acquired knowledge may be applied.

With this instruction in mind, the following account is offered of our methods of obtaining information on accidental injuries. The magnitude of this one class of morbidity may be judged by the fact that we calculate there were 47 million injuries in a year which resulted in medical consultation, or in restriction of the person's usual activity. Of this number, 40 percent were home injuries.

This calculation is based upon a scientifically designed sample of the population of the United States. The count from the sample was expanded to give a national estimate for which we can measure the margin of error due to the sampling procedure. From among 1,900 counties or groups of counties into which the whole country is divided, 500 are obtained in the first stage of sampling. Further sampling stages yield the final units, called segments, each of which contains about six dwelling units where the interviewer knocks on the door.

Dr. Lawrence, chief of the Household Survey Analysis Section, National Health Survey Program, Public Health Service, presented this paper at the 46th National Safety Congress in Chicago, October 22, 1958.

Interviewing is done continuously throughout the year, but each week's sample is a representative sample of the Nation. This makes it possible to produce weekly estimates of events that occur often in the population, or to combine weekly samples to obtain quarterly or annual estimates for less frequent events or for subgroups of the population.

About 6,000 segments, or 36,000 households containing roughly 115,000 persons, are included in the interviews during the course of 1 year. These households are scattered through every State, but the sample is not designed to produce individual State estimates. One year's data will provide estimates for 12 major geographic sections; for 8 metropolitan areas; or for all of the metropolitan, urban, rural, and rural-farm divisions of the Nation.

The interviews are conducted by 125 interviewers who are under the guidance and supervision of the Bureau of the Census. The data are obtained according to specifications of the Public Health Service. In a program of this kind the question of reliability of the basic data is of primary importance. For this reason numerous controls are built into the program for the purpose of maintaining quality. Interviewers are selected by examination and are further selected and trained in several steps, including group sessions and supervisor's observation of practice interviews. Several times each year refresher courses are given both interviewers and supervisors. Once each month interviewers are given written examinations. The survey also includes, as a continuing procedure, re-interviews by the supervisors of about one-sixth of all households. A final evaluation of interview quality is made at the data-processing stage where errors and omissions by each interviewer are

BCG Vaccination

What now are the disadvantages? Even in the face of grossly diminished need, BCG vaccination would be justified if it offered complete protection. Carefully conducted and controlled studies, here and abroad, yield sharply conflicting evidence on this point. Studies in this country do the least to affirm the usefulness of such vaccination. Not only are there doubts regarding the benefits of BCG, but there are complicating factors as well. Probably the most important is that BCG causes tuberculin sensitivity, making it virtually impossible to differentiate by skin testing between persons who have been vaccinated and persons who have been infected with virulent tubercle bacilli.

Other problems would result from the general use of BCG vaccine. Any appreciable increase in nonspecific reactions to tuberculin would obscure the measurement of trends of tuberculosis infection, the search for source or index cases, and the selection of groups of younger people for X-ray screening. Also, a valuable tool in differential diagnosis would be lost to us.

—RALPH E. DWORK, M.D., *director of health, State of Ohio.*

Our hypothetical interviewer has already asked whether the person has consulted a doctor. She is now ready to find out about other actions taken, and she proceeds with several questions: "Last week or the week before did this injury cause you to cut down on your usual activities for as much as a day?" "How many days?" "How many of these days were you in bed all or most of the day?" "How many days did the injury keep you from going to work?" In the case of a child, "How many days did it keep him from going to school?" Our interviewer then asks whether the person has any of several types of permanent or long-lasting limitations of activity or of mobility. Finally she inquires about the person's hospital experience.

We consider a positive response to any of these questions as a form of disability. In other words, we define "disability" as any temporary or long-term reduction of a person's activity. The criterion of the least severe disability in our data would be 1 full day of restriction of usual activity which did not involve confinement to bed. From this point further degrees of severity of disability can be defined, depending upon whether there were bed days, hospital days, or some type of chronic limitation. School-loss days or work-loss days refer to special population groups, children or persons who usually work.

Information on disability is of primary interest to many people. It is around some concept of disability that programs are often planned and that the economic consequences of ill health or injury are often measured. The word "disability" is not only widely used but has taken on a wide variety of meanings for the purposes of different kinds of programs. I do not want to describe the many different ways by which disability is classified. It is important to note, however, that tabulations which include, or exclude, injuries on the basis of different definitions of disability are almost certain to lead to different estimates of the rate of occurrence of injuries. Reports of injuries by various organizations may all be reliable, but they still may differ because of the sources of data and the definitions employed.

In the National Health Survey interviews, respondents report to us all degrees of injury.

However, we tabulate and publish information only on injuries for which the person consulted a doctor or which caused the person to cut down on his usual activities for at least 1 full day. Injuries of this degree amount to about 56 percent of all injuries or 51 percent of the home injuries that the respondents have told us about. We, as well as others, have been surprised at the large volume of injuries shown in publications from the National Health Survey. Yet these figures include little more than half of the injuries originally reported to us in the household interviews.

What the Survey Can and Cannot Do

From this account of the way in which the survey is conducted and how injuries are measured, it is apparent that there are many questions that cannot be effectively answered by the household survey of the National Health Survey Program.

First, we cannot estimate the number of accidents because we have no way of connecting together several people who may have been injured in the same accident. We can estimate the number of injuries or the average number of persons injured.

Because we use a 2-week recall period we cannot count the number of people who had any given number of accidents during a period of say 1 year. We cannot, therefore, study the question of accident-prone individuals.

The National Health Survey cannot provide any detailed epidemiological information such as the circumstances that led up to the accident, or the kinds of equipment, or names of products that were involved. Epidemiological research of these types can be, and should be, made by smaller, more intensive studies which might employ sources of data other than a household survey.

The survey covers only the experience in the preceding 2 weeks of people who were living at the time of the interview. For this reason the survey cannot supply information about injuries that result in death within a few days of the accident. The kinds of fatal injuries, the amount of hospital and physician care required, and the circumstances of the fatal accident must be obtained from other sources.

routinely tabulated and transmitted to regional supervisors. During other steps of data processing, further controls are applied. For example, all coding of medical conditions is done independently in duplicate. The codes are then compared and differences are corrected.

The Questionnaire

Interviews are conducted with a responsible adult in the home, with the requirements that all adults present at the time must be interviewed for themselves and that no one may be the respondent for any unrelated person. The interviewer does not ask about deceased members of the household. Therefore, we do not obtain data on injuries from which the person died within a few days after the accident.

Assume that an interviewer has called at a dwelling place. She has asked about the composition of the household and has obtained for each member such personal characteristics as relationship, age, sex, race, marital status, and education. She now asks a series of questions to get information about the presence of current illnesses, injuries, chronic diseases, or impairments. Among these questions there are three which are most likely to reveal an injury condition. "Last week or the week before, did you have any accidents or injuries, either at home or away from home?" "Last week or the week before did you feel any ill effects from an earlier accident or injury?" "Does anyone in the family have any of these conditions?" After the last of these questions, the interviewer slowly reads a list which includes impairments such as deafness, serious trouble with vision, amputations, paralysis, and any permanent stiffness or deformity of any part of the body.

These questions result in two types of measurement of accidental injury. One type consists of the prevalence of impairments or aftereffects of accidents that occurred at some time in the past. The other is the incidence, or rate of occurrence, of new accidental injuries within the preceding 2 weeks. To measure the incidence of injury, a 2-week recall period is used. Two weeks was selected as a reasonable time interval during which people can remember the occurrence of acute conditions or

injuries. Studies have indicated that longer recall periods result in loss of information. Since about half of the tabulated injuries in this survey were reported as having occurred "last week" and half the "week before," there appears to be very little memory loss for injuries within a 2-week period.

Assume that the respondent has reported some sort of accidental injury. Our interviewer records the condition and then asks additional questions to define further the nature of the injury. She asks, "Did you ever talk to a doctor about it?" "What did the doctor say it was—did he use any medical terms?" "What kind of injury was it?" "What part of the body was hurt?"

Having defined the kind of injury, the interviewer asks about the time and place of the accident. "When did it happen?" "Where did it happen?" "Was a car, truck, bus, or other motor vehicle involved in any way?" "Were you at your job or business when the accident happened?" These questions permit us to separate accidents which happened in or about the home from other types. They further define whether the accident itself occurred in the preceding 2 weeks or whether the condition reported is an aftereffect of an earlier accident.

Information is not obtained as to how the accident happened. We know at this point, for example, whether it resulted in a burn or a fracture or an amputation, but we do not know whether the immediate cause was an explosion, a fall, or a collision. The kind of information needed to classify accidents by type cannot be accurately obtained from a few brief questions. In our aim to provide a panorama which includes many areas of health and medical care we have had to sacrifice some information on each topic. However, information on the type of accident will be obtained in a future addition to the questionnaire.

Measuring the Effects of Injuries

The principal advantage of the household survey method is that certain types of information can best be obtained from the people themselves. This is true with respect to the effect illness or injury has on their lives and what actions they take in relation to these conditions.

Group medical practice as an innovation depends for acceptance or rejection on how those involved in it perceive it. If these perceptions conflict with the individual's behavior and ideas, there is clearly a need for understanding and action.

Provision of Medical Care

History • Sociology • Innovation

GEORGE ROSEN, M.D., Ph.D.

WHEN the Committee on the Costs of Medical Care published its final report in November 1932, the majority submitted a program with five basic recommendations. The first of these proposed "that medical service, both preventive and therapeutic, should be furnished by organized groups of physicians, dentists, nurses, pharmacists, and other associated personnel. Such groups should be organized, preferably around a hospital, for rendering complete home, office, and hospital care. The form of organization should encourage the maintenance of high standards and the development or preservation of a personal relation between patient and physician" (1). The more sanguine proponents of this course of action felt that group medical practice was a logical and reasonable step toward improved organization and provision of medical care, and that it would spread rapidly. But this did not happen.

Organizations designed to provide medical care through some form of group practice have

developed slowly but steadily in the intervening 25 years. Some have been organized by consumers using the Rochdale principles of co-operation. Others have been created by groups of physicians in noninsured practice, by labor unions, and by groups in the community who wish to make comprehensive medical care available to low- and middle-income groups. A number of these are associated with prepayment plans, notably with the Health Insurance Plan of Greater New York and the Kaiser Foundation Health Plan.

Recently, questions have been raised concerning the slow growth of such plans, and critical views have been expressed on the gap between promise and practice in group medical care (2-4a). These critiques have highlighted certain painful inadequacies and have focused attention on the importance of solving these problems, but the proposed remedies tend to concern themselves with surface manifestations or to dissolve in hortatory admonitions. In a discussion of the quality of medical care at the recent National Conference on Labor Health Services, one participant remarked: "When people leave a group practice program to join a fee-for-service plan . . . the gauntlet has been thrown down to the service plan. There must be reasons for this, because workers generally reflect the degree of satisfaction with the serv-

Dr. Rosen is editor of the American Journal of Public Health and professor of health education at the School of Public Health and Administrative Medicine, Columbia University. This paper was presented to the medical care section of the American Public Health Association, St. Louis, Mo., October 29, 1958.

We cannot provide clinical or detailed diagnostic data. A respondent probably could not tell us that he had a Colles' fracture of the radius, but he could tell us that he broke his lower arm. Yet detailed diagnostic information might be needed, for example, in a program which aims to develop protective equipment.

Finally, within its present scope, the National Health Survey is unable to obtain estimates of injuries for individual States, counties, or communities. A city which desired to obtain illness or injury information from its own population sample could, however, employ methods of interviewing and of questionnaire design similar to those of the survey.

It is evident that there are many things about home injuries which we are not prepared to answer and which should be answered by other methods or by local research projects. However, there are some types of information that can be more effectively obtained by this survey than by any other present methods or sources.

One distinct advantage is that the national survey can provide information along broad baselines. For some years there has been a tendency to generalize the results of small studies to apply to the Nation as a whole. With a national sample we now have, or will soon have, estimates of injuries and other conditions for the Nation, for major geographic regions, and for a number of urban and rural population groups. The sample not only provides information on ill and injured persons, but on the characteristics of the population in which the cases occurred. This makes it possible to produce rates of occurrence for urban or farm groups; for different educational or income classes; by marital status; by usual activity; or for other subgroups of the population.

Since the program is on a continuing basis,

the survey can obtain time trends for data that have a seasonal or cyclical pattern. The continuing nature of the survey may also be an asset in periodic measurement of health factors that could change as a result of preventive programs, new techniques or increased use of medical care, or changes in national economic conditions.

One other advantage of the household survey method has already been touched upon. This is the capability of ascertaining the effect of the injury on the person's life in terms of disability. Information on disability is important for motor vehicle injuries and for work injuries as well as for those which occur in the home. However, the household survey method is particularly useful with respect to data on home injuries. Information on motor vehicle injuries of certain degrees of severity can be obtained from official reports. Data on work injuries, at least those of an industrial nature, are obtainable from records and reports of industries. Hospitals have certain data on persons who are injured severely enough to come through their doors. But for the great bulk of home injuries there has been no centralized source of information. Many of these home injuries are of a less severe nature, but they nevertheless constitute a sizable part of medical care needs, of lost time from work, and of bed disability.

As time goes on the National Health Survey Program will publish increasing amounts of data on home injuries. It is hoped that these data will be useful to people engaged in safety programs by helping them to assess the extent of the problem, by providing information on various characteristics of persons injured in home accidents, and particularly by stimulating research and program planning in this very important aspect of the health of the people.

Poliomyelitis Packet

A poliomyelitis packet designed to help health departments promote immunization programs is available without charge from the Communicable Disease Center, Atlanta, Ga. Samples of the packet have been sent to State health departments.

groups as well. Nonetheless it remains a phenomenon to be taken into account in studying the development of new methods for providing medical service.

Medical Ideology and Practice

The physician as we know him today in the United States and in other countries is a relative newcomer. The general practitioner is some 200 years old in this country, and about 100 years in Great Britain (5, 6). The 19th century also saw the appearance of the general practitioner in France and Germany out of the fusion and elimination of several categories of practitioners. The modern specialist made his appearance around the fifties and sixties of the last century (7). Most characteristic of these practitioners from a social and economic viewpoint was that they were individual, small entrepreneurs, members of the middle class. As small entrepreneurs, they shared the socioeconomic attitudes and views of other middle-class groups. (Social and economic class as used in this discussion refers to configurations of behavior—occupational or productive activity, life styles, patterns of consumption, political and other belief systems—which exhibit a sufficient degree of consistency to make it possible to distinguish from one another groups in the social organization of a community. This does not imply that social and economic classes are homogeneous layers in a social structure. This is particularly so in the case of the middle class. Initially, in the medieval urban communities a somewhat cohesive social and functional group of merchants, tradesmen, and artisans, it has undergone changes in the course of history. New alignments and tensions between various intermediate economic or social groups have led to such essentially historical designations as the older and the newer middle classes. Among the various component elements of the middle class may be counted middle-size entrepreneurs in industry and trade, small shopkeepers, professionals such as the physician, lawyer, and teacher, and officials and salaried employees. According to the Oxford English Dictionary, the term "middle class" was employed in 1812, and John Wade, in 1833, refers to the "middle classes" (8-13).)

The fact that these practitioners were small entrepreneurs and shared the socioeconomic attitudes and views of other middle-class groups has been most clearly evident in the United States. The social philosophy of liberalism, combining the ideas of Adam Smith and Thomas Jefferson, provided the ideological framework for these attitudes. The task of government was to provide the fundamental security needed for community life, especially the protection of property, but government action was to be kept to a minimum. There was little or no need for a strong central authority, because local government could handle most community problems. As far as possible, it was felt, the individual should be free of regulation and given full scope for individual initiative. While certain undertakings required joint action within the community, each man was held to be entitled to carve out for himself the largest possible stake.

The American physician of the 19th century shared these views with his neighbors and acted accordingly. Each man was sufficient unto himself, except as he adhered to rules of professional behavior established by his colleagues. Competition was accepted as natural and was quite brisk. According to William J. Mayo: "Competitive medicine was the response of the individual physician to his training and environment. It fostered self-sufficiency and jealousy" (14). The physician ran his practice from his office, with little recourse to the hospital or to complicated equipment.

Social Change and Group Practice

Since the end of the 19th century, and to an increasing degree following the First World War, this self-sufficiency has been undermined. The physician and his practice have become inextricably intermeshed with the increasingly complex social organization which exists for the provision of medical care. In this process the hospital has come to occupy a central position. (This association of the physician, particularly the general practitioner, with the hospital occurred to a much greater degree in the United States than in Great Britain or on the continent. For all practical purposes, the general physician has not been a member of the

ice" (4b). And while the speaker conceded that there may be multiple reasons, these apparently derived simply from the lack of "the amenities, the niceties, the timeliness, the promptness, the personal touch," or something desired by the patient. There is no apparent appreciation that such phenomena may be symptomatic of more deeply rooted causes. Furthermore, while this speaker and others dealing with this problem give evidence of an empirical awareness that medical care is a social activity organized in certain institutional forms, there is no reference to the existence of a body of scientific theory and knowledge which may throw light on the problems previously indicated, and perhaps point to ways of mastering them.

Medical care in some form has been an element of group living throughout history, and in all likelihood long before recorded history. Moreover, as a social function it is integrated and interlocked with other elements in the structure of group living of which it is a part, with government, the economy, the family, religion, and others. All human actions must be studied within a framework conditioned by men, with an understanding of men's ideas of the present and hopes for the future. Historical continuity derives from common challenges and purposeful responses to meet these challenges. One such constant has been the continuing search for security from the unpredictable impacts and hazards of ill health and its concomitants. Another aspect of continuity is the human aspiration toward self-fulfillment, the individual's need for self-expression. Such needs may reinforce each other or run counter one to another, thus creating tensions. The result is a variety of actions and reactions under differing circumstances and in widely divergent ideological climates. Yet these actions and reactions provide a pattern which makes possible an understanding of behavior and process. For a major contribution of historical analysis is to penetrate the process of development. Institutions, patterns of behavior, systems of ideas, methods of control—all have developed from something which was there before. The hospital, the health department, fee-for-service medical practice, the theory of animate contagion—all illustrate this truism which is too

often forgotten. For these reasons it may be useful to consider group medical practice in historical and sociological terms, and to see whether historical analysis and sociological investigation may not enhance our understanding of its present condition.

Sociology, History, and Medical Care

The provision of medical service is an activity involving interaction between two or more human beings, thus creating a social system. At the same time, the participants in this system are also members of other larger and smaller social systems, which form the greater part of their environment, and which exert a determining influence on their thought and action. Without knowledge of this environment, the behavior of the physician, of the medical profession, of the patient and his family, and of others involved in the provision of medical care cannot be fully understood and taken into account in changing traditional ways of providing medical care and adopting new forms for this purpose. Within this environment, there is a social order characterized by differential distribution of power, accessibility to ways of earning a living, prestige, and status. The participants in this order have defined roles, specified behaviors considered appropriate to these roles, and values which motivate or are presumed to motivate the participants. Associated with this system, supporting it and interlocking with it, are complexes of knowledge, techniques, beliefs, values, attitudes, norms, symbols, rituals, and customs. Some of these are shared widely in a society; others are the concern of smaller groups.

The medical profession, like other occupational groups, has a body of shared ideas, values, and standards. Members of the profession are expected to orient their behavior in relation to patients, colleagues, and the community at large in terms of norms and values generally accepted and agreed upon. Many of these ideas and behavior patterns have been transmitted from the past and are adhered to even though the situation has changed radically. Adherence to systems of inappropriate or incompatible values and norms is not peculiar to physicians; it is characteristic of other

for the development of self-reliance and the achievement of success. Under the impact of expanding industrialism in the United States, the medical profession joined other middle-class groups in accepting this philosophy and applying it to questions of public health and medical care. Theoretical justification for refusing to use tax funds for the expansion of public health work, or for the provision of medical care and other aid to the poor, was sought in the Darwinian theory of evolution. Disease was a special case of the struggle for existence, and one of the means by which the fittest survived (20).

Today, the principle of State intervention and control in health matters is generally admitted, although variations may exist in practice due to the greater or lesser efficiency of the intervention and in the greater or lesser frankness with which the role of the State is admitted. Its emergence has come from the interaction of important economic and social trends. For one thing, during the period from the end of the 19th century to the present, the trend of economic organization has been the continuous and progressive replacement of smaller units by larger ones. The further this process advanced the more untenable has become the conception of noninterference by the State. But while other elements of the middle class, for example, the small businessman, sought protection against the large producer and competitor through government action, the medical profession was able to continue relatively untouched by change in the privileged sanctuary of private practice. And for the most part its ideology has remained intact.

The *Chicago Medical Journal and Examiner* wrote in 1879: "It is frequently stated that the poor should be protected by the government against the causes of disease which are said to infest the habitation of the lower classes. . . . It is the lazy people and their sentimental friends who are always calling for government aid. If now you undertake to protect this fraction of the community, you have to protect it against the consequences of idleness, luxury, intemperance and vice—thus interfering with the operation of the wholesome monitory laws of nature; and you do it at the expense of the meritorious classes of society. Having accus-

toried such worthless people to rely upon government for protection against smallpox, and scarlet fever, and syphilis, and diphtheria, and sewer-gas, and scabies, it will not need the passage of many generations before they will demand protection by the government against the cold and hunger and nakedness for which they should themselves make provision" (21).

The same gentle spirit still pervaded the editorial views of the *New York State Journal of Medicine* in 1949 (22, 23): "Any experienced general practitioner will agree that what keeps the great majority of people well is the fact that they can't afford to be ill. That is a harsh, stern dictum and we readily admit that under it a certain number of cases of early tuberculosis and cancer, for example, may go undetected. Is it not better that a few such should perish rather than that the majority of the population should be encouraged on every occasion to run snivelling to the doctor? That in order to get their money's worth they should be sick at every available opportunity? They will find out in time that the services they think they get for nothing—but which the whole people of the United States would pay for—are also worth nothing."

Heresies

From the last decades of the 19th century to the present day, a variety of "heresies" in the financing and organization of medical care have been opposed with ideological weapons obtained from this philosophy. Dispensaries, free public clinics, contract medical schemes, and prepayment medical care plans have all aroused opposition and have been met with similar arguments. The abuse of medical charity agitated physicians and their organizations from the 1880's onward (24, 25). Allegedly, free clinics for the poor were being used by others less deserving of charity, who would consequently be "pauperized." To the concern with free clinics and their effects was soon added the problem of contract schemes, and just before the First World War came the movement for national health insurance. These innovations were opposed on the ground that they subsidized the inefficient and the lazy, they destroyed the personal relation between physician and patient, they decreased professional com-

hospital staff in Britain or in countries such as Germany, Austria, or France. The movement to exclude the general practitioner from American hospitals is a recent development and has led to various countermeasures.)

The practitioner must depend on expensive equipment, as well as on specialists and technicians for diagnosis and treatment. The situation was strikingly illustrated by Dochez in a comparative picture of the complex changes wrought in medical practice over three decades (15). He contrasted the histories of two patients with similar types of heart disease; one was recorded in 1908, the other at the same hospital in 1938. The total written record of the first patient occupies 21½ pages and the observations represent the combined efforts of 2 physicians, the attending and the house officer, and of 1 specialist, the pathologist-bacteriologist. The record of the second patient, who was still in the hospital when Dochez made this comparison, comprised 29 pages and represented the combined observations of 3 visiting physicians, 2 residents, 3 house officers, 10 specialists, and 14 technicians, a total of 32 individuals.

Today, the medical practitioner must have some hospital connection, both for his patients and for himself (16-19). The fledgling physician is no longer apprenticed to another physician, but to a bureaucratic institution, the hospital, where he serves as intern and resident. Furthermore, he must depend on relations with other medical men to get started in practice and to keep a clientele. Throughout his career, hospital appointments are crucial to his practice and to his advance in some medical hierarchy. To a considerable degree, the referral mechanism is controlled by informal cliques in hospitals. At the same time there has been an increase in the number of ancillary occupations filled by persons on a salaried basis. One major consequence of this system has been to narrow the area of practice (the market) of the general physician, and to imply, often correctly, that he is not competent to handle a number of types of illness.

These trends and facts underlie the behavior of physicians in relation to various forms of prepaid and organized medical care: Blue Cross, Blue Shield, prepayment group practice plans, hospitals, union health plans and cen-

ters, and above all, government action in the health field. Viewed and interpreted sociologically, the behavior of a large part of the medical profession represents the reaction of a segment of the older middle class to the process which is compelling it to come to terms with modern industrialized society. To use an analogy, one may say that medicine is experiencing its Industrial Revolution, and that the medical practitioner is being brought into the "factory" (the hospital and the whole complex organization for the provision of medical care), where he is being subjected, on a privileged basis, to the requisite "labor discipline."

Competition and Survival

The entire profession and its field of action are undergoing change, but different kinds of practitioners face varying situations. The general physician endeavors to keep hospitals, specialists, and other organizations and individuals concerned with medical care from competing with him and limiting the area of his activity in ways which he considers unfair. This aim is implicit in the establishment of the Academy of General Practice, of general-practice departments in hospitals, in the idea of an American Board of General Practice, and in the opposition to review and control of the quality of medical care offered by prepayment organizations and welfare funds. The general situation also affects the specialist, who wishes to maintain the status quo so that his privileged position will not be altered. He endeavors to render ineffective any threatened competition. Considerations of this kind, whether overt or covert, are involved in the insistence on free choice of physician, on fee-for-service practice, and in all the other battle cries that have echoed on the medical care battlefields for more than four decades.

But while the self-sufficiency of the physician as entrepreneur is undermined by the march of science, technology, and social organization, the ideology of competition and rugged individualism still remains the uncompromising official creed. According to this ideology, the solitary individual, endowed with personal merit, makes his way against others in the open market. The effort involved in this competitive process provides, it is believed, the condition

adequate capital resources might not have been available. After all, the Health Insurance Plan started with loans from several foundations, and it is noteworthy that the only other group practice plan of comparable size (Kaiser Plan) started on an industrial base. Furthermore, are there any inherent limitations in group practice as an organizational form? The answer must be that we do not know.

Nonetheless, there are hints from investigations concerned with the sociology of bureaucratic organizations. Some of the problems brought about by the size of an organization have been studied. Tsouderos, for example, in examining 10 voluntary organizations, found that the introduction of more formal procedures and greater specialization of function, as organizations grow, tends to alienate a number of individuals (29). The emergence of a heterogeneous membership can also be an outgrowth of the increasing size of an organization. Such a development carries with it the probability that the members will have dissimilar views on various matters. This in turn can lead to a decrease of consensus (30). However, none of these studies has been concerned with medical care plans, and one may suggest that group practice could be a fruitful area for research.

Role Performance

By virtue of the process of socialization, the physician acquires a scale of values, a set of attitudes, and a way of thinking and acting which is distinctive in various respects. Some of these are traditional and represent the "conventional wisdom" (to borrow a term from J. K. Galbraith's book, *The Affluent Society*) of the medical profession. As part of this process, there develops a professional self-image, a definition of the physician's role, which enables him to carry out his obligations under a variety of circumstances. In some environments, the performance of this role is more visible than in others and consequently more easily available for control (31). The physician in his private office is subject chiefly to the controls of the professional values and norms, to his concept of himself as a professional person, and to what he considers good practice.

These controls are buttressed in varying degree by sanctions both within and outside the profession, such as expulsion from a medical society or a malpractice action. Otherwise, the physician in his office is not very visible in performing his role, except to patients usually unequipped to pass sound judgment on his action in technical terms.

Some environments are so structured that the practitioner is under the continuing scrutiny of others who appraise the way in which he performs his functions. This is true of the hospital, with its requirements for records, arrangements for staff conferences, consultations, and other accepted responsibilities. What is true of the hospital can apply equally in a prepayment group practice plan or in a labor union health center. In such organizations, the practitioner's behavior not only is visible to his colleagues, but is or may be scrutinized by prepayment plan officials or welfare fund administrators. Furthermore, there may not be agreement on the standards by which performance is judged. In any event, what exists in these organizations is a mechanism for social control which makes him subject to pressures of various kinds. Where the limits of observability in the medical situation are to be drawn is not easily determined, but it should be obvious that physicians strongly imbued with an individualistic ideology will not easily accept the controls involved in more complex types of medical care organization. (The problem is not limited to the performance of physicians and others involved in the provision of medical care. Similar problems confront members of the teaching profession (32).)

This thesis is based on Robert Merton's concept of the role-set, that is, the "complement of role-relationships in which persons are involved by virtue of occupying a particular social status" (32). In the case of the physician and his status, this entails not only the role of a practitioner vis-a-vis a patient, but also an array of other roles relating him to his colleagues in a medical group, to nurses, laboratory technicians, health plan administrators, medical societies, and the like. The relationships physicians have with persons in each of these positions are by no means identical, and involve situations calling for differing attitudes

petence, they were unethical, and similar arguments which still ring familiar.

It is clear that not all physicians shared the official view. For example, in 1889, J. L. White proposed a prepayment plan by which physicians would contract to provide services, emphasizing preventive care, for families for an annual fee (26). The following year a prepaid medical care plan was actually initiated in Chicago by J. K. Crawford and Oscar DeWolf, but the Chicago Medical Society condemned the two physicians (25b). Later, a small group in the American Medical Association also favored compulsory health insurance, but they could do little in the face of the dominant opposing view (27). To a certain extent, such innovating individuals and groups have been favored by periods of rapid social change and reform. This was true during the first decade of the 20th century, the era of progressivism, and to a certain extent during the New Deal thirties.

Under the threat of a national system of health insurance, voluntary health insurance has developed and spread. At least in principle, the American Medical Association has accepted prepayment group practice. Furthermore, a large part of the medical profession, about one-third, today works wholly or in part for salaries (in hospitals, medical schools, for other physicians, government agencies, unions, and pharmaceutical companies).

Continuing Tradition

Nonetheless, the emphasis is still on individual responsibility for medical care, fee-for-service solo practice, and free choice of physician. And even though the medical practitioner may not wholly subscribe to the philosophy, policies, and practices of the professional groups that represent him or speak in his name, he cannot help but be bound by these rules, at least in some measure, whether or not he is aware of this.

In becoming a member of his profession, the medical practitioner undergoes a process of socialization, involving not only the acquisition of knowledge and skills, but even more significantly, perhaps, the acquisition of the values, attitudes, and behavior patterns that enter into and make up the physician's role. Even when the practitioner deviates from the

dominant values, attitudes, and behaviors of his profession, he rarely breaks completely with them. In considerable measure, his relations with his patients may still be determined by these elements, even when he practices in a different setting, for instance, in a medical group. Numerous elements of his role will still be appropriate in this new setting; others, however, are either totally or partially dysfunctional. As a consequence, working in a group practice setting requires changes of attitude and behavior resulting from the acquisition of new goals, reference groups, and relations with colleagues, patients, and other involved persons and groups.

Some forms of change are socially approved. Physicians, for example, are expected to keep abreast of new developments in medicine and related fields so that medical practice can be carried on at the highest possible level. Even here, tradition may exert a restraining influence. Change in the provision of medical care is not generally sanctioned by the groups that set the rules for medical behavior; indeed, it has occurred against strong opposition. Unless there is some compelling reason, change is not easily or lightly undertaken in such a situation by any group of people. During the Second World War, a considerable number of younger physicians in military service were apparently interested in group practice upon returning to civilian life (28). As is well known, however, they did not flock into group practice. While a number of factors were involved in this development, it appears likely that many of these physicians simply took the traditional path because it was easier, coinciding as it did with several other developments, among them, economic prosperity, a rise in the standard of living, social disapproval of nonconformity, as well as legal barriers to prepayment group practice. (This is an interesting problem for social research.)

Here one may ask: Would group practice have increased more rapidly had these conditions not existed? Obviously, such a question is difficult, if not impossible, to answer. Group practice requires the investment of capital to begin with, and that it be available when needed. It may be that even if the physicians had wanted to organize group practice units,

others will see the group practice in the same way. Yet the actual members, the patients, in a group practice plan are more likely than not to be a heterogeneous group—teachers, firemen, machinists, government workers, bus boys, and so on—with diverse expectations and attitudes in terms of past experience, educational background, ethnic origin, social class, and the like. In HIP for instance, it was assumed on rational grounds that it would be more advantageous to all concerned to provide medical care through medical group centers. Yet, the only concrete experience that many workers have had in receiving care from anything resembling such a center is in clinics and outpatient departments of hospitals, of health departments, and similar agencies. Such services still have a “charity” connotation, or at least a lower status association for many people. Experiences in such facilities explain also “why outpatients feel like outcasts” (47). For such people, to receive care in a physician’s private office is a step upward, and any move to bring them into a situation such as prepayment group practice with medical care provided in a facility which can be related to the objectionable clinic will be resented. Naturally, this does not apply to all, but there are enough people to whom it does apply and who make themselves heard. One may suggest that this is one of the factors behind the dual choice arrangement now offered by the Kaiser Foundation Health Plan and by the Health Insurance Plan of Greater New York. In short, the definition of the situation by the patient cannot be assumed to coincide automatically with that of the physician or of the health plan administrator. They may even run counter to one another.

Conclusion

Like the public health and social welfare movements, the movement for prepaid medical care in the United States was originally conceived and implemented chiefly by middle-class people, even though intended to benefit members of a lower social class. Motives of social amelioration propelled to action the proponents of such schemes as prepayment group practice, who were acutely aware of the economics of medical care and the social consequences of lack of care. Furthermore, members of the middle

class are future oriented, prepared to forego present satisfactions in order to achieve future goals (48). Great value is placed on health as a means to an end, and the use of rationally calculated means to reach such a goal. Small wonder, then, that financing and administration have been the major concerns of the movement for increased and improved medical care. This is clearly evident in the otherwise excellent volume, *Readings in Medical Care*. But just as the Sabbath is made for man, so medical care is financed and organized to provide service to people, who whether one likes it or not are not all alike and do not all share the same goals, values, and norms. The health education program of the Health Insurance Plan, for example, is based on a recognition of this premise (49, 50).

Only recently, however, has there appeared an explicit awareness of the central relevance of social science for the provision of medical care. Patients, physicians, administrators, union leaders—all have certain value orientations, behavioral characteristics, class memberships which are important factors in determining how medical care programs operate and what their outcome will be. The closer to the habitual the more easily accepted. Group medical practice as an innovation depends for acceptance or rejection on how those involved in it perceive it. If these perceptions conflict with the individual’s behavior and ideas derived from his class position, there is clearly a need for understanding and action. Certainly, this is an area for research and the implementation of the resulting knowledge.

This analysis has touched on a number of points and has endeavored to indicate a framework—historical and sociological—within which group medical practice must be seen, if its problems are to be understood. There is a full awareness on my part of the possibility and the need for even more intensive analysis of various points. However, as the objective of this analysis is solely to call attention to important dimensions of the medical care problem and to stimulate thought and action concerning the ways in which significant contributions might be made to improved medical care, there is plenty of opportunity to occupy the energy and ingenuity of others.

and behavior. Patients, for example, will differ from physicians in their expectations of the medical practitioner to whom they come for care. Furthermore, not all those in the particular role-set are involved in the same way or in the same degree, and it is important to know what various participants in a role-set bring to it.

Social Class and Therapy

Ideally, the role performance of the physician in relation to a patient centers in impartially serving the patient's health needs regardless of any liking or antipathy he may have for the particular individual. Like all ideals, however, it is only approximated in reality; and this is true in solo practice as well as group practice.

The practice of medicine is affected by the social class system. That the physician is a member of the middle class has already been pointed out, and whether or not he is aware of it, much that he does is influenced by the element of social class. A number of studies in the United States and in other countries highlight the significance of class considerations. Diagnostic and therapeutic decisions, for example, are influenced by the social distance between the practitioner and the patient. Some physicians are either intuitively aware of this factor or have learned by experience to take it into account. In many instances, however, there is no awareness of the distance separating physician from patient, and consequently no attempt is made to narrow this gap.

Aubrey Lewis has pointed out that the psychiatrist and his patient usually share the same subculture, and can therefore define the situation and the problem in a mutually acceptable manner (33). This point has been made more explicit by a number of empirical investigations, which show that patients with mental illness who most nearly approach the practitioner's social class are likely to receive psychotherapy rather than organic therapy or no treatment and are more likely to be considered hopeful from a therapeutic viewpoint (34, 35). Williams has called attention to the need for taking into account the class premises of the patient. If this is not done in psychiatry, dif-

ferences in the perception of problems and their solution may lead to incorrect diagnostic conclusions (36).

Class perceptions and values of the patient may likewise affect practitioner-patient relations. In Regionville, for example, Koos found that members of the lower class felt that physicians were not particularly interested in them as patients. He further reported "a lack of communication between the physician and his patient. Part of this lack was due, no doubt, to the fact that physician and patient too often represent differing subcultures, and 'speak different languages'" (37-39).

Such observations are not limited to the United States, but have been reported from other countries, such as England and France (40, 41). Furthermore, members of the lower social class are less likely to use child health clinics, have their children immunized, or use medical care services when they are members of a prepayment plan. Differences of this kind are likely to be accompanied by differences in expectations concerning illness and therapy. Persons in lower income groups, especially families of unskilled workers, are subject to a number of limitations which affect their behavior with respect to preventive medicine and medical care. For one thing, the horizon of this group is severely limited by fear, ignorance, and misunderstanding, as well as by different types of reaction to life situations. This is true not only of health (42, 43). There is some evidence to suggest that the unskilled English worker feels that his ability to influence the course of events is severely limited. Consequently, there is less stress upon the individual's responsibility (44a). Furthermore, actions are confined generally to the needs of the moment, and the future is allowed to take care of itself. Working class families also tend to be suspicious of authority, and the official health agency may personify this (44b, 45).

Orientation to upward mobility may be another factor which affects the patient's reaction to medical care organization. For example, proponents of group practice feel that this way of providing medical care simultaneously meets the needs of both patient and physician (46). Behind this idea is the implied premise that patients, physicians, administrators, and

Methodology Research Award

The deadline for nominations for the Eighth Kimble Methodology Research Award is June 1, 1959. The award, \$1,000 and a silver plaque, is given annually in recognition of the application of scientific knowledge to the public health laboratory.

Candidates from the United States, its Territories, and Canada will be considered. They may be nominated for making a fundamental contribution which serves as a baseline for the development of diagnostic methods within the province of a public health laboratory or for the adaptation of a fundamental contribution which makes it useful in a diagnostic laboratory.

The Kimble award, established by the Kimble Glass Co. of Toledo, Ohio, and sponsored by the Conference of State and Provincial Public Health Laboratory Directors, will be presented at the annual meeting of the conference in Atlantic City, N.J., in October 1959.

The rules governing nominations can be obtained by writing to Dr. E. T. Bynoe, chairman, nominating committee, Kimble Award, Laboratory of Hygiene, Department of National Health and Welfare, Ottawa, Ontario, Canada.

account for more than 60 percent of the increase in the total estimate for 1956. Medical care expenditures are 5.2 percent of all personal consumption expenditures in the revised series as compared with 4.5 percent in the old series.

The revisions are the result of new benchmarks and newly applied techniques for estimating personal consumption expenditures, and indicate changes in the distribution pattern of personal consumption expenditures. A detailed description of the technical aspects of the new series will appear in the Department of Commerce publication.

The revisions for commodity categories, such as drug preparations and sundries, and ophthalmic products and orthopedic appliances, are based on new Census of Manufactures and Census of Business benchmark material for 1954 and census survey data for 1950 and 1956, in place of the former preliminary extrapolations of the 1947 benchmark data.

Service categories, such as physicians and dentists, are now based on current Internal Revenue Service data for gross receipts in tax returns for the period 1953-56, in place of extrapolations from earlier income figures.

Medical care as a percentage of the consumer dollar, that is, the dollar spent for goods and services, increased considerably between 1929 and 1957, but at an uneven rate. Reduction of economic activity in the depression years was reflected in a drop in the dollar volume of expenditures for medical care from \$2.9 billion in 1929 to just under \$2 billion in 1933, although the proportion of medical care to total personal consumption expenditures increased from 3.7 percent to 4.3 percent. From 1933 to 1948, the proportion vacillated between 4.0 and 4.3 percent, then began a steady rise. By 1957 medical care represented 5.3 percent of the consumer dollar, a rise to 140 percent of the 1929 ratio of 3.7 percent and the highest percentage on record.

Personal consumption expenditures for medical care by type of product, current and old series, for selected years, 1929, 1933, 1948, 1950, 1952-57¹—Continued

for 1952-56 from U.S. Office of Business Economics: Survey of Current Business, National Income Number, July 1957, table 30, p. 21. New series from U.S. Office of Business Economics: U.S. Income and Output, 1959, table II-1, pp. 150-151.

Personal Consumption Expenditures for Medical Care

Estimates of personal consumption expenditures for medical care items have been revised by the National Income Division of the Office of Business Economics in the Department of Commerce. The expenditure figures, which have been revised back to 1948, are being issued early in 1959 in U.S. Income and Output, a special supplement to the *Survey of Current Business*. They will appear in table II-4 in place of the previous table 30.

Below and on the next page are tabulated the personal consumption expenditures for medi-

cal care by type of product, in dollars and in percentage, for 1929 and 1933, which are unchanged; for 1948, 1950, and 1952-56, which have been revised; and for 1957, which are in the current series.

For 1956, the revised total of personal consumption expenditures for medical care is almost \$2 billion higher than the earlier total. Of that increase, \$1 billion, or more than 50 percent, is the result of upward revisions in estimates for drugs and sundries expenditures; \$600 million, or 31 percent, for dentists; and \$200 million, or more than 10 percent, for ophthalmic products and orthopedic appliances. Drugs and other commodity categories in the medical care expenditure estimates together

This material was prepared by Lucy M. Kramer, research analyst in the Division of Public Health Methods, Public Health Service.

APHA CONFERENCE REPORT

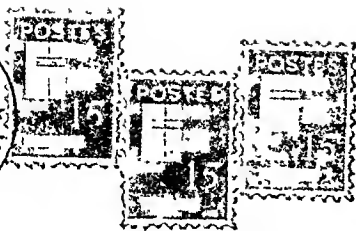

SUMMARIES OF SELECTED PAPERS
from the 86th annual meeting
of the
AMERICAN PUBLIC HEALTH ASSOCIATION
and related organizations
held at St. Louis, Mo.
October 27-31, 1958

Consolidation for Strength

Public health agencies in defining public health criteria and procedures are not keeping pace with the new developments. Thus, there is an increasing tendency toward splintering public health responsibility and authority and the dispersion of essential services to various existing or newly created agencies. If this trend continues it will undermine the influence of professional public health leaders and destroy the unity of health programs necessary to effectiveness. In order to meet this basic challenge, the public health profession needs to augment its strength as a whole with emphasis on particular areas of activity. In my judgment, it is essential that we restudy the strategic position of public health and shape our programs to increase their influence on public policy and counteract the trend toward scattering responsibility. . . .

In many cases in the past support and protection for health programs have been obtained largely by personal and emotional appeals. For example, the people have faith in the health officer as an individual and move to his aid when he needs the pressure of public opinion. Such emotional appeals are uncertain of results and likely to be transitory in their effect. We must develop on a sound scientific basis continuing programs of public relations and health education that will be effective in advancing health services on their own merits.

ROY J. MORTON, C.E.
President, American Public Health Association
From the presidential address, October 28, 1958

A Vessel for Chiloe

We are taking steps to obtain an 80-foot vessel to serve as a marine clinic for some 40,000 people who live on remote islands or inlets in Chiloe Province.

The province, 650 miles south of Santiago, Chile, has one of the country's highest general and infant death rates. About 25,000 of its inhabitants live in small towns on the mainland.

A doctor, a dentist, and sanitation aides use a 50-foot boat, purchased by the National Health Service 2 years ago, to visit some 15,000 others living in sheltered inlets or on nearby islands. But most of the people are receiving no care. Only a larger craft, with quarters for a crew and medical staff, can travel for several days through the rough seas and stormy weather of latitude 40° S. to reach these islands.

—G. HOWARD GOWEN, M.D., *chief public health adviser, U. S. Operations Mission, Chile.*

M.D.'s for Vietnam

Despite formidable handicaps, the medical school of the University of Saigon is training increasing numbers of the physicians Vietnam needs. The country has only 350 for its 12 million people; of these, 160 are in government service, 160 in military service, and 30 in private practice.

When Vietnam was partitioned in 1954, the mixed faculty of medicine and pharmacy moved from Hanoi, where its main physical plant was located, to Saigon. Classes were scattered to temporary quarters in 17 different locations in the city. Enrollment soared, reaching more than 500 students, too many for the school's permanent teaching faculty of 30.

Assistance from the U. S. Operations Mission has been concentrated on increasing the teaching staff and providing adequate physical facilities. Young faculty members receive fellowships to study abroad to prepare for teaching careers in medicine. Visiting professors from the United States come to

Saigon to assist in developing understaffed departments. The Vietnam Government agreed to defer some young physicians from their obligatory military service immediately upon graduation so that they can accept fellowships, and when they are inducted later, to assign them, as their military duty, to teach at the medical school.

The 6-year curriculum was changed to allow for a regular internship in the 5th year and a rural internship at a provincial hospital in the 6th year. A contract to construct a Saigon medical center, with a basic science building and a teaching hospital, is being negotiated.

—CRAIG S. LICHTENWALNER, M.D., *public health physician, medical education project, U. S. Operations Mission, Vietnam.*

The Engineer

The water supply system of Manaus, Brazil, a city of 100,000 at the fork of the Amazon and Negro Rivers, has been under reconstruction under Serviço Especial Saúde Pública auspices for many years. Because funds for the work came from third parties, progress was irregular. Most of the money was spent on pumping and distribution facilities. Water treatment could not be started until distribution was widened, enabling the system to increase its rates and, consequently, its income.

However, 6 months after the city hired a competent engineer and gave him the authority to operate the system, water revenues tripled and they continue to increase. The system will soon be paying for itself.

—E. ROSS JENNEY, M.D., *chief, Health and Sanitation Division, U. S. Operations Mission, Brazil.*

Salt Monopoly

The Bank of the Republic, which holds the salt monopoly in Colombia, is contributing to food research. Bank officials in compliance with a decree will give one centavo from the sale of each pound of iodized salt manufactured and sold in Colombia to the National Institute of Nutrition. The institute will use the funds, which may total 3 million pesos annually, to improve the nutrition of the Colombian people.

—VERNON B. LINK, M.D., *director, Public Health Division, U. S. Operations Mission, Colombia.*

suburbs and rural-urban fringe areas, an absence of adequate building code standards means that the slums of the future are being built now.

- About 27 percent of the annual housing output has been constructed by do-it-yourself builders. Most of this building is the poor man's response to high construction costs. However much these efforts stir one's admiration, it must be admitted that they now add appreciably to the difficulties of assuring proper standards of design, location, and construction. They present a difficult and delicate problem that has been largely neglected.

- Local taxes and debt have increased phenomenally. Taxes in suburbs and fringe areas are now commonly as high as or higher than the tax rates in central cities or large suburbs with full complements of public facilities and services. The outstanding local government debt increased 107 percent for 1950-57.

- In suburban and fringe localities, tax bases are markedly disparate. Some local government units must tax according to a property tax base consisting almost entirely of modest housing, while across a boundary line another government unit is profiting from a major shopping center or industrial plant. Very little benefit accrues to the former government units from the proximity of shopping centers or industrial plants. This result is a direct consequence of the "Balkanization" of local governments in metropolitan areas. In 1957, the 174 standard metropolitan areas (6 were added since 1950) had 15,658 units of local government, an average of 90 per metropolitan area.

- Plans have been inadequate for the development of parks, playgrounds, forest or wildlife preserves, public beaches, and libraries. Land has not been reserved for these uses at a time when one of the principal forces contributing to urban dispersal is the increase and wider distribution of leisure time.

- The landscape has been butchered by bulldozer, chain saw, short-sightedness, inexperience, public apathy, and commercial cupidity.

Warnings

Woodbury added three warnings as guides in the consideration of these matters. Dispersal, he said, is not the cause of growth problems. It is an active factor, but more pertinent are our antiquated systems of local government finance, the irrational hit-or-miss character of governmental structures in metropolitan areas, high construction costs, neglect of ways and means to facilitate the education of in-migrants in the difficult processes and manners of urban living, and the common neglect and downgrading of local public issues, he declared.

The faults of current urban dispersal, Woodbury said, are not inherent in the process itself, but arise from the planless, shortsighted, stupid ways in which much of it is carried on. The tragedy, he commented, is that most migrants to the suburbs are realizing only a part of the gains they might make and at costs many of which either are not necessary or are unnecessarily high.

But the alternative is not, as some advocate, relatively high-density, largely apartment-type development, he said, adding that this would be a 19th century solution and inappropriate to our times.

Microbes Wed to Wastes By Selective Process

Almost every water pollutant can be degraded by one form of microbe or another, but selecting the right microbe is not an easy matter, declared Dr. Paul W. Kabler, chief of microbiology, Robert A. Taft Sanitary Engineering Center, Public Health Service.

Selection, he said, takes place by fortuitous matching of potentially competent micro-organisms with appropriate waste materials. Further adaptations are accomplished by

producing necessary new enzymes either through activation of latent characteristics or through genetic changes that arise spontaneously or by stimulation from environmental factors.

Kabler pointed out that the new industrial wastes joining soil or aqueous environments are confronting organisms with chemical entities in concentrations and under conditions not previously known. With some of the newer organics, Kabler said, selection of the proper organism has not yet been completely successful, but there appears to be no reason why suitable organisms should not be found if the search is sufficiently diligent.

Artificial and natural purification, Kabler observed, are accomplished by the combined metabolic activities of a number of species and variants selected and adapted from an infinite number of micro-organisms and micro-environments existing in nature. Adaptation, he explained, is a function of the microbes' ubiquity and the activity of those best suited to a given environment; those less suited lie dormant waiting for the right environment.

Enzymatic adaptations, he said, are not usually retained by an organism when the compound is removed from its environment, and the transfer of adaptive qualities in one generation to the next does not involve changes in the genetic pattern. Each cell has the genetic ability to produce the enzyme but does so only when the stimulating material is present. The elaboration of an enzyme when it is useful and the ability to grow without it when it is of no value appear to be the basis for much of the on-the-spot adaptation of microbes, Kabler averred.

Radar and Rocket Fuel Pose Few Hazards

The biological effects of microwave energy emanating from radar sets and the toxic effects of rocket fuels were discussed in the context of oc-

The APHA Conference Report

With the assistance and cooperation of the authors, the staff of *Public Health Reports* has summarized some 90 papers presented at the 86th annual meeting of the American Public Health Association and related organizations held in St. Louis, Mo., on October 27-31, 1958.

Summaries were selected for publication in the following pages to present in one volume a representative body of facts and ideas dis-

cussed at the conference. Omitted from these selections were papers scheduled for early publication in the *American Journal of Public Health*, papers whose authors provided no copies for the press, and certain others which for one reason or another were not suited to summarization.

A few papers omitted from this selection are under consideration for publication in full in subsequent issues of *Public Health Reports*.

Edge of the Future . . .

Prefers "Dispersal" To Urban "Sprawl"

In considering some of the effects of urban expansion on housing and community growth, Dr. Coleman Woodbury, director of urban research at the University of Wisconsin, pointed out that urban sprawl is a loaded term. Who, he asked, could possibly find any merit in a phenomenon labeled "sprawl," a term redolent of clumsiness, immaturity, and ridiculousness?

Whatever the conceptual differences between sprawl and dispersal, the characteristics of current urban growth in all parts of America are the same, and involve, he observed, the more or less planless extension of urban building on and on into the countryside with little or no attention to community facilities and services, topography, future transit and transport problems, and so on.

Characteristics

Woodbury cited estimates of the U.S. Bureau of the Census which reveal that 95 percent of the population increase in the United States

from 1950 to 1956 occurred in the 168 standard metropolitan areas and urban areas in their vicinities; the metropolitan areas, excluding urban areas in their vicinities, accounted for 85 percent of the population growth. Furthermore, he said, if we accept the fact that a large proportion of nonurban metropolitan areas are urban in employment, orientation, and ways of life, then national population growth is almost entirely urban.

Woodbury broke metropolitan areas into three subareas: central cities, suburbs, and rural-urban fringes. Increases in population during 1950-56 for these three subareas were 15.6, 27.2, and 41.5 percent, respectively. In other words, he said, over a recent 6-year period, more than two-thirds (68.7 percent) of the national increase went into population areas outside their central cities, and more than two-fifths into metropolitan areas outside of both central cities and suburbs.

Nearly all of the rural-urban fringes and many of the suburbs, Woodbury averred, are poorly prepared in governmental structure and finances, customs and traditions,

civic organization, and even in prevailing attitudes to take care of this flood of in-migrants and their needs.

Another characteristic of urban dispersal, Woodbury observed, is the concentration in central cities of poor newcomers unskilled in urban vocations and living. More and more suburbs, he said, are now in the middle and lower middle income ranges, and the old image of the suburbs as predominantly bedroom towns of the wealthy and well-to-do is no longer valid.

Problems

Woodbury identified seven problems that urban growth and dispersal are forcing on the attention of those concerned with the future of housing and local community development.

- The concentration of low income in-migrants in central cities and the relative decrease and slower growth of some economic activities there result in a relative reduction in per capita tax-paying capacity in central cities. At the same time, there is a greater need for more services and expenditures for health protection, housing, recreation, police, welfare services, and schools in central cities.

- In many large and growing

Beginning with the LD₅₀ test on rats for toxicity of ingested chemicals, the toxicological laboratory of the company screens all products for hazards. To measure irritability to the skin and eyes, a single large dose is applied to the skin of a rabbit and kept in contact for 24 hours, and a small amount is dropped in a rabbit's eye. Liquid products are vaporized, and test animals are exposed to controlled concentrations until systemic toxicity appears. As indicators of effects of

chronic exposure, rats experience the vapors for periods up to 8 hours. The laboratory also conducts a routine test of subacute toxicity by adding controlled amounts of the product to the food of animals for 30 days.

If the product is a solid there is likely to be little or no vapor. Skin and eye data indicate the possibility of toxicity on contact. If handling of a product creates dust, workmen can be protected from inhaling toxic amounts by safety gear.

under the committee on mental health, and sufficient funds were allocated for its operations.

In 1955, the committee on mental health was raised to the status of council, and the subcommittee on alcoholism was raised to the status of a full committee.

Results Enumerated

What have been the committee's accomplishments? Block summarized a number of them:

- Two well-received exhibits were built. They are available for AMA conventions and for meetings of all State and county medical societies that request them.

- Interest in alcoholism has been stimulated in the State medical societies. Whereas few State medical societies had committees working on the problem before the committee on alcoholism was formed, 37 States now have such committees.

- In 1956, four articles, written by members of the committee, appeared in the *Journal of the American Medical Association* on the medical, psychiatric, physiological, and sociological aspects of alcoholism. In 1957 the articles were bound with additional information and issued as a manual for the use of general practitioners.

- At the request of the committee, the AMA purchased a complete set of the Abstract Archives of the Alcohol Literature, which has enabled the committee to answer a flood of queries on the subject.

- In 1956, the AMA House of Delegates passed a resolution, submitted by the committee on alcoholism, urging all general hospitals throughout the country to admit alcoholic patients to their general medical floors. This represented a tremendous victory, Block said, for it meant that "the largest medical organization in the world had now recognized alcoholism as a disease which warrants admission to general hospitals for those people suffering from it."

- In 1957, the committee produced a directory of rehabilitation resources, listed by States, and

Mental Health and Alcoholism . . .

AMA Action on Alcoholism Reported by Dr. Block

The family physician is in a unique position to find cases of alcoholism and to prevent its more serious sequelae, but he must first be informed of his responsibilities, observed Dr. Marvin A. Block, chairman of the committee on alcoholism of the American Medical Association.

Block recounted the history of the AMA's efforts in calling the attention of the Nation's physicians to the health problems of alcoholism, transferring the disease thereby from a social to a medical priority.

He recalled the early efforts of an eminent physician in Erie County, N.Y., who, in 1948, having observed the successes of Alcoholics Anonymous, placed the problem of alcoholism within the province of medicine. A medical committee was formed under his instigation to stimulate the interest of physicians, and he helped create a citizens committee whose purpose was to educate the public about alcoholism as a medical disease, and the possibilities of treatment and rehabilitation. Block said.

Summit Action

In 1950, this physician, seeking concerted national action by his fellow physicians, brought his ideas be-

fore the AMA House of Delegates, which passed a resolution establishing a committee on alcoholism within the commission on chronic illness. The following year, Block said, a committee on the problems of alcoholism was appointed as a subcommittee of the chronic disease committee, but no appropriations were passed, with the result that the subcommittee never met.

In 1952, a year after the subcommittee had been appointed, its members were informed that the subcommittee had been disbanded. The subcommittee, Block said, promptly asked for the appointment of a new committee and an appropriation of funds.

Sequel Recounted

During this time, Block said, the lay committee on education on alcoholism was functioning very well; it had become affiliated with the National Committee on Alcoholism, and, as a result of its actions, a rehabilitation center for alcoholics was established by the University of Buffalo Medical School.

In 1953, the executive secretary of the AMA committee on mental health was invited to visit the medical school's facilities and to discuss the possibility of forming a subcommittee on alcoholism. The upshot was the creation of a subcommittee

cupational health by Colonel George M. Knauf, surgeon at the Air Force Missile Test Center, Patrick Air Force Base, Fla.

So far, he said, all evidence suggests that any detrimental effects are thermal and occur only at certain intensities and frequencies. Power produced by present equipment does not attain the maximum safe exposure level of 0.01 w./cm.² beyond 500 feet from the point of origin. It therefore poses no threat to residents in the vicinity of radar sites. And common sense precautions preclude injurious exposure in operating and maintenance personnel, Knauf said.

Research, Knauf reported, has revealed the following facts about the effects of microwave energy:

1. Few biological injuries have been observed from exposure to this energy above 3,000 megacycles.

2. The crystalline lens of the eye is the tissue most sensitive to microwave energy; exposure can result in opacities of the lens. But such opacities have not been observed with exposure to power levels below 0.12 w./cm.² regardless of the length of exposure.

3. Some evidence of an accumulative effect has been found.

4. Some evidence exists of an electrical effect on nerve impulse propagation by exposure to extremely high frequency energy. (This may be of value in diagnosis and treatment of selected neuromuscular diseases.)

5. Certain tissues, such as red bone marrow, are heated by microwave energy. (This, too, may be of therapeutic interest.)

The principal concern of industrial medicine with regard to rocket fuels, Knauf pointed out, is the fact that chemicals formerly used in reagent-bottle quantities are now being used in tank-car quantities. Moreover, he said, ordinary drivers of refueling trucks are handling enormous quantities of extremely potent chemicals, whereas trained laboratory personnel, oriented to the hazards of these chemicals, formerly handled them.

Aeromedics Paving Way For Safe Space Flight

Television in a spaceship might be the answer to the debilitating effects of monotony on the pilot, observed Major Stanley C. White, flight surgeon, and Captain Charles L. Wilson, aeromedical examiner and research physician, in their discussion of the physiological problems of space flight before the American College of Preventive Medicine session.

White and Wilson are in the Aero Medical Laboratory at the Wright-Patterson Air Force Base in Ohio.

Overcoming monotony is just one problem facing the physician, whose main concern, along with the engineer's, is getting the pilot safely back home, White and Wilson said.

Other conditions posing questions for the medical profession are:

- Thermal dangers when spaceships leave and re-enter the earth's atmosphere.

- The necessity of reconditioning exhaled gases within the sealed cabin of the space vehicle.

- Gaseous swelling of tissues unless adequate pressure is applied to the pilot's body in the cabin.

- Sudden decompression in the cabin's artificial atmosphere which would explode the pilot's body into the vacuum.

- Oxygen toxicity or hypoxia if the oxygen supply is too much or too little.

- Stress of rapid accelerations, reaching 8 g and maintained for 200-250 seconds. This accelerative force is equivalent to putting a 50-pound weight on the chest and 100-pound weights on the extremities, leaving only the fingers free to move.

- Psychological and physiological hazards associated with weightlessness, which occur when the earth's gravitational pull no longer prevails.

- Radiation belts around the earth which must be penetrated without danger to the pilot if the mission is to succeed.

Some of these problems have already been solved, White and Wil-

son said. A pressurized suit worn by the pilot avoids the hazards of decompression and inadequate pressure. These suits have an emergency system that automatically responds to the loss of atmosphere in the cabin and inflates the suit in a split second.

Stresses of rapid acceleration are overcome by breathing with the stomach, lying in a position with head and feet slightly elevated, and controlling instruments through digital manipulation alone, they said.

White and Wilson also said that chemicals such as lithium hydroxide recondition exhaled gases by combining with both carbon dioxide and water vapor.

Solutions to the hazards of radiation in space and of weightlessness are still being sought, they concluded.

Synthetic Resins Aid Health Techniques

Advances in techniques of health services by use of synthetic resins, described by L. J. Francisco of the American Cyanamid Company, include disposable syringes, tubing for catheters, and microscope slides and covers.

In heart and vascular surgery synthetics replace parts of veins, arteries, and valves and have been more successful than tissues grafted from another person.

At the Jewish Hospital of Denver, Francisco said, polyethylene foam is used to fill the chest cavity of a patient whose lung has been collapsed.

In food-processing plants, commonly built of unfinished concrete blocks, resin is sprayed inside the building to check the growth of bacteria. In fluid form, it penetrates, fills, and smooths the rough and porous surface.

Chemicals that are characteristically inert are more suitable for packaging and at the same time least likely to be toxic, Francisco stated.

said, are records of mental hospitals that admit and treat alcoholics. These records, he commented, contain data on the social, economic, and psychological background of problem drinkers.

Equally useful, he said, are the records on unemployment-disability compensation. What brings individuals to claim disability, the types of illnesses or injuries for which such disability is claimed, the repetitiveness and the length of such claimed disabilities are all useful clues in the search for the manner in which alcoholism takes its social, clinical, and economic toll. In 1953, Lipscomb said, California found that disabilities associated with the use of alcoholic beverages were the recorded cause of 1 percent of all claims paid, and that, for men, these claims almost equaled the number paid for malignant neoplasms. Alcoholism represented well over two-thirds of the total alcohol-associated disability claims paid.

Each State, Lipscomb observed, has an industrial accident commission with a large data-collection machinery, which includes judgments on individuals injured on or off the job. These judgments frequently follow medical consultation and advice and are, therefore, another rewarding source.

Lipscomb also referred to the advantages that would accrue from a thorough study of mortality and morbidity data, not merely for the unique populations of mental hospitals, skid rows, and prison farms, but for the population as a whole, to determine the influence of alcohol on survival and illness. He also considered the rosters of social welfare agencies as a rich source of information on the effects of intemperate drinking.

Epidemiology

In California, Lipscomb said, the focus of the State health department has been on the accumulation of as many measurable clinical and behavioral resource units related to drinking practices as possible. From this accumulation it has attempted

to obtain a composite description of the group characteristics of drinkers.

Not all persons falling into these units (for example, divorce, penal records, and drunk arrests) are problem drinkers, he said, and it is not enough for the epidemiologist simply to gather descriptive data. In the epidemiology of alcoholism, Lipscomb said, it is vital to order and use these measurements as chronological markers in the development of problem drinking, to validate current etiological studies, and to predict those groups at increased risk of developing alcoholism.

Puts Control of Alcoholics Up to Health Agencies

It is the ultimate objective of the State department of public health to make treatment of alcoholic patients a part of general medical practice within each community, and the control and prevention of alcoholism a part of community health services.

Dr. John R. Philp, chief of the division of alcoholic rehabilitation, California State Department of Public Health, made this point in an historical discussion of California's activities in alcoholism.

According to Philp, California's concern with alcoholism dates back to 1870 when the board of public health was first established. The board at that time was instructed to examine the effect of intoxicating beverages upon the citizens of the State.

In 1937, California provided for the hospitalization in mental hospitals of dipsomaniacs, inebriates, and addicts to stimulants. It was quickly demonstrated that, at most, those committed represented a tiny portion of the alcoholics needing treatment, although alcoholics entering mental hospitals soon comprised one-fifth of all admissions, Philp said.

Following a study of drunkenness in San Francisco in 1948, the first treatment clinic for alcoholism in California was established: the San

Francisco Adult Guidance Center in the health department of the city and county. Another clinic was established the following year in the Alameda County Rehabilitation Farm at Santa Rita, Philp commented.

In 1949, Philp recounted, the Governor's Conference on Mental Health devoted a section to alcoholism and recommended the designation of an agency to carry out the responsibilities of the State in this regard.

Thus, in 1954, after further study, the California State Alcoholic Commission was established by the legislature to deal with all phases of the treatment and rehabilitation of alcoholics. With a budget reaching \$700,000 annually, the program included research, treatment, rehabilitation, and public information and education. Six pilot clinics for the rehabilitation of alcoholics were created during the commission's life, in addition to a program in two private nonprofit hospitals to demonstrate the advisability and feasibility of hospitalizing the acute alcoholic as a part of the hospital's general medical service. Pamphlets, documents, and newsletters were published by the commission, and its grants supported research and the San Francisco Adult Guidance Center, Philp said.

In 1957, the commission was abolished by the legislature, and its program, budget, and civil service staff were transferred to the State department of public health. The department was charged with the responsibility of engaging in the treatment and rehabilitation of alcoholics and in the reduction and prevention of alcoholism. A division of alcoholic rehabilitation was created within the department to undertake these duties.

Since 1957, Philp said, the new division has been administering, with minor modifications and adjustments, the program inherited from the commission. At the same time, he pointed out, it has been developing a long-range plan for consideration by the legislature.

available from the AMA national headquarters.

- Two surveys were initiated in 1958, one on teaching about alcoholism in medical schools and the other on the laws relating to alcoholism in the States. Eventually, the committee hopes to formulate a uniform law applying to the handling and disposition of alcoholics, Block said.

- The committee hopes to induce Blue Cross to pay hospital benefits for alcoholics.

- Other activities have been promoted in the last 4 years to educate the medical profession on alcoholism. This has included conferences and institutes. Each institute consists of five speakers, members of the committee on alcoholism, who deliver lectures on the medical, psychiatric, physiological, and sociological aspects of alcoholism. It is a half-day's program which is presented only on the invitation of a State medical society. All expenses for these institutes are borne by the American Medical Association.

Block concluded by pointing out that the individual physician can no longer avoid the issue of alcoholism as a medical responsibility. He must treat patients who have become problem drinkers, and he must, here as in other diseases, seek to prevent alcoholism, for the answer to this problem, Block said, lies in prevention rather than therapy.

Preventive Medicine Helps Mental Cases

Reorganization of Ohio's mental health program to accent public health and preventive medical services was described by Dr. John D. Porterfield, Deputy Surgeon General of the Public Health Service.

The first step in the reorganization, Porterfield said, was to establish a public health unit within the office of the director. The unit was then staffed with a sanitarian, a nutritionist, and a physician who was trained in chest diseases, particularly tuberculosis.

The physician was named health officer of the department and given two major functions: first, to serve as consultant specialist in preventive medicine to all institutions, and second, to give particular attention to the extensive problem of tuberculosis in the mental institutions, Porterfield said.

The nutritionist, he said, had a full-time job of seeing that the inmates were fed properly within stringent budget limitations, that the food was aesthetically wholesome, and that the food would give the most mileage to the penny, reducing at the same time the garbage disposal problems.

To effect economies in the organization and procedures of the statewide food service operation, the nutritionist established a central kitchen in which recipes and menus were pretested for their adaptability in 100-portion lots, Porterfield said. This step permitted purchasing in bulk many items previously bought by each institution in small quantities, with concomitant savings. The central kitchen, Porterfield observed, also served as an excellent training facility for food-service personnel.

By devices such as this, he said, the nutritionist earned her annual salary almost monthly in both food savings and food-service improvements.

The problems of the sanitarian ramified from the agricultural occupations of the inmates. A long-range program was begun to improve abattoirs and meat-processing facilities, milk production and processing, and canning of food crops so that they would prove "an asset rather than a threat to the patient," Porterfield commented. The sanitarian also had the monumental task of attempting to provide adequate washing and toilet facilities for the huge population residing in antiquated buildings.

Developing screening mechanisms to uncover early signs of chronic degenerative disease in the inmates was considered by Porterfield to be a rare opportunity. Not only did

it mean improving their physical health and prognosis, he said, but it also meant improving their psychiatric prognosis.

Asks More Illumination On Intoxication

Twice as many drinkers as non-drinkers were involved in fatal automobile accidents in California, an analysis of traffic accidents in 1955 revealed. Investigations of a finding such as this, declared Dr. Wendell R. Lipscomb, division of alcoholic rehabilitation, California State Department of Public Health, are sorely needed.

The discouraging thing about the personal consumption of alcoholic beverages in this country, he said, is how little is known about it. Citing the need to know the who, how, when, and where about the use of distilled beverages, Lipscomb suggested several sources of epidemiological data. The purpose of collecting the data, he pointed out, is to help identify the problem drinker so that the basis for sound interventional and preventive measures may be established.

No single average drawn for the country as a whole can meaningfully dictate the proportion of drinkers in any particular city, he observed, adding that to obtain the proper information, one must study the distribution of alcoholic beverages and then investigate each community. The pattern of drinking may then be related to data on mortality and morbidity.

Sources for Data

However difficult it may be to compare one area with another because records and definitions of alcoholism vary from place to place, within any given community there is a surprising consensus as to what constitutes an arrest for drunkenness, or a crime or traffic accident that is related to the use of alcohol, Lipscomb averred.

Other sources of data, Lipscomb

discharge from a hospital must precede nursing home care, Brewster added, nursing home cases have amounted to about one-fifth of 1 percent of all cases and one-half of 1 percent of all days of care. The average stay in the nursing home has been about 30 days, and the cost per day about the allowed amount of \$8.

Prepaid Prescription Plan Organized in Ontario

A voluntary prepayment plan for prescription medicine has been organized in Canada by W. A. Wilkinson, a pharmacist and president of Prescription Services, Inc., a private, nonprofit body in Windsor, Ontario.

Started in January 1958, with March 1 the first effective date, the plan has grown from 65 subscriber families for the first month to 244 for the fifth. Although financial success is not yet assured, Wilkinson cited two trends which he believes indicate that such a plan is feasible:

- A plateau for prescription price seems to have been reached.

- A plateau of use seems to be in the offing.

Average prescription price times use rate will establish a premium, and if this premium can be kept within reason, we can produce a popular policy, he declared.

The average prescription price, Wilkinson said, seems to have leveled off at about \$3.50 per month. The monthly use rate has dropped from 0.655 to 0.386, and he expected it to level off at about 0.250.

Now serving Essex County in Ontario, the plan, if successful, will be extended to the rest of the Province, according to Wilkinson. Seventy-five pharmacies, 64 in the Windsor area, are currently members. As a condition for membership a pharmacy must lend the corporation \$150, repayable in 10 years without interest. Subscriber membership is available only through groups, with 75 percent of a group participating.

A major problem, Wilkinson admitted, has been selling the service to eligible groups. The invalid have clamored to join, because pre-existing conditions are not excluded, but many well people, never having spent much for medicine, have felt they would not benefit. Employees have tended to look to their union to obtain the service for them, and management has frankly opposed giving another "fringe benefit," he pointed out.

On the brighter side, Wilkinson reported little evidence of cheating by patients. Abuses can be spotted, he said, by examining the pharmacists' charge cards, and a warning that the service will be canceled helps to stop them.

The service covers only drugs prescribed by physicians and dispensed by a member pharmacy. For various reasons, medicine dispensed or administered by physicians, medicine prescribed by dentists, insulin and diabetic supplies, vitamins (except those designated "therapeutic vitamins"), and parenterally administered drugs are not covered, Wilkinson stated.

Psychiatric Care Included In Labor Health Plan

A psychiatric program has been operating successfully since 1946 in the St. Louis Labor Health Institute, a group practice prepaid medical care plan serving some 15,000 union members and their families, according to Dr. Louis L. Tureen, one of three psychiatrists working part time for the institute.

As a member of the plan's medical team, the psychiatrist acts both as a consultant to the medical staff and as therapist to individual patients, Tureen reported. About half the patients referred to the psychiatric service for diagnostic appraisal, he pointed out, are returned to the referring physician for continued medical care.

Treatment, geared to the medical needs of the patients, but necessarily

limited by the economic framework of the organization, includes supportive therapy, suppressive therapy, and dynamic psychotherapy, the psychiatrist said. The first two types are predominant, primarily because of the limited psychiatric time available (20 hours a week), he indicated.

Tureen explained that supportive therapy, frequently accomplished in 1 or 2 interviews, emphasizes relief of distress and anxieties. He described the aim of suppressive therapy as "amelioration of symptoms," rather than resolution of conflicts. Sedatives, inhalation of carbon dioxide, and even electroconvulsive treatment are used in addition to interviews.

Interview periods average 25 to 30 minutes. However, Tureen emphasized, to make the most effective use of the time available, a "chronic supportive case" may be given only 10 to 20 minutes while a patient with a good many personality assets is allotted 40 or 45 minutes.

Only a few patients are hospitalized, he reported, although the plan allows up to 30 days' hospitalization for psychiatric patients.

From an analysis of the case histories of 471 patients selected at random during an 8-year period, Tureen concluded that "3 to 10 visits is the most fruitful and economically feasible program" for the St. Louis Labor Health Institute. Of the patients making 1 or 2 visits (40 percent), only about 20 percent showed improvement, whereas for those making 3 or more visits, the proportion was 75 percent. (Only a few made more than 10 visits.)

He also concluded that psychosomatic disorders (which affected 89 of 320 nonpsychotic patients) are best suited to the "brief superficial therapy" possible in the psychiatric facilities of LHI.

Other classifications for the nonpsychotic patients were psychoneurotic reactions (181 patients) and personality disorders (50 patients). In addition, among the 471 patients there were 90 with neurological problems, 49 classed as psychotic,

Prepayment Plans . . .

Home Nursing Care Given Subscribers in New York

A 5-year experiment in New York City indicates that provision of home nursing service, following hospitalization, as a health insurance benefit is feasible, reported Maria Phaneuf, nurse coordinator, Associated Hospital Service of New York. Her organization, New York's Blue Cross plan, conducted the study in cooperation with 4 hospitals and 5 visiting nurse associations.

In addition to promoting the well-being of the patients, the first objective of the experiment, provision of the nursing service reduced costs of illness by shortening hospital stays, Phaneuf stated.

For the first 500 patients receiving the service, hospital stays were shortened by 7,948 days, according to the physicians' estimates, even though the average stay was 27 days. This reduction, she emphasized, meant an estimated saving of \$152,000 after payment of \$25,000 for the home nursing service. About half the saving accrued to Blue Cross and the other half to the patients.

The reduction in length of hospital stays also meant the release of hospital facilities. Phaneuf determined that 700 patients could have been hospitalized for average stays of 11 days in beds not needed by the 500 patients. Assuming an 80 percent occupancy, 26 hospital beds were made available through use of home nursing service, she added.

About three-fourths of the 500 patients were under private medical supervision, and about the same proportion were 45 years old or older. Nearly two-thirds suffered from one or more long-term illnesses.

The home nursing service was an elective alternative to further in-hospital care, Phaneuf explained. Moreover, use of home service in no way altered the amount of inhos-

pital service available to each subscriber in his contract with Blue Cross.

Discussing organization of the program, Phaneuf called it "an experiment in cooperation between voluntary hospitals, visiting nurse agencies, and Blue Cross for better service to the patients and the community." Written agreements between the participating organizations outlined responsibilities.

The visiting nurse agencies were paid by the hospitals at the agencies' community rates, and Blue Cross reimbursed the hospitals.

Now authorized by New York State law to provide care only in or through hospitals, Blue Cross has requested an amendment to permit payment for home care, including nursing service, appliances, drugs, medicines, supplies, and ambulance service, Phaneuf concluded.

Syracuse's Approach

In Syracuse, N.Y., the Visiting Nurse Association is focusing its attention on major medical insurance, which some of its patients now carry, announced Mabel F. Chrystie, executive director of the association.

Patients of the VNA with major medical insurance numbered 14 in 1957 and 28 during the first half of 1958, Chrystie said.

At present, the Syracuse VNA is participating in a local unit set up "to develop mutual understanding between the insurance companies, the industries insured, and those who provide the services covered." In addition, the following steps have been taken, the nurse reported:

1. Space added to the family service record for recording information about major medical insurance.

2. A card file set up for information about each plant or company insured (including a copy of each insurance manual) and about the local offices of the insurance carriers.

3. A card file developed for recording experience of individual patients.

4. A special billing form devised for use by patients in obtaining insurance reimbursements.

Considering the phenomenal growth of prepayment plans to date, the enormous potential for group coverage in Syracuse, and the increasing emphasis on home care, we expect major medical insurance to be a source of income for the VNA, Chrystie declared.

Six Hospitalization Plans Cover Nursing Home Care

At least six Blue Cross plans are providing coverage for nursing home care, stated Agnes W. Brewster, medical economist with the Social Security Administration.

Describing briefly the nursing home benefits offered, she noted that each plan has at least one of the following limitations:

1. Contracts are offered only to groups, which excludes most retired and elderly persons.

2. Beneficiaries must be discharged from a hospital directly to a nursing home, a provision which tends to confine cases to certain diagnoses.

3. A limit on benefit days during a lifetime.

4. A co-insurance provision, with the patient paying 20 percent of the nursing home charges.

Brewster indicated also that no completely satisfactory scheme has been worked out for determining what are acceptable institutions for the beneficiaries.

Concluding with statistics on use of nursing homes, she reported that under the Philadelphia Plan, which limits benefits to 30 days in a lifetime, the number of nursing home cases has amounted to only one-half of 1 percent of all cases since 1951. The cost per day of nursing home care was a little more than half the cost of a day of hospital care, she said.

Under the Delaware Plan, where

interested union were given complete dental examinations, including full-mouth X-rays, prophylaxis, and clinical examination.

Assuming inclusion of service for all accumulated dental needs in the first year's contract and 100 percent utilization, it is estimated on the basis of the surveys that the first year's premium would vary from \$60 for a plan limited to examination, prophylaxis, X-rays, fillings, and extractions to \$300 for comprehensive coverage, Beebe said. However, he added, the survey of treatment needs suggests a utilization rate nearer 50 percent, which would halve the per capita premium.

So far, the scope of a specific dental care plan has not been discussed with any consumer group. Nor has a final fee schedule been presented to participating dentists or a prospective group purchaser.

Any plan the corporation sponsors will be an open panel plan, with all interested dentists participating, Beebe said.

Full Dental Cost Insurance Awaits Public Demand

Insurance for comprehensive dental care on a broad scale awaits public demand, stated J. F. Follmann, Jr., director of information and research, Health Insurance Association of America, New York City. Interest now is localized mainly among labor unions, some employers, public health officials, and dental societies.

Dental costs in 1953, he said, were from \$45 to \$95 for 10 percent of the families in the Nation, from \$95 to \$195 for 6 percent, and more than \$195 for 4 percent.

Reviewing current types of insurance coverage for dental expense, he pointed out the trend toward covering only work resulting from accidental injury or that performed in hospitals. Expansion of in-hospital coverage is inhibited by the lack of concise contractual definitions, the hazard of unnecessary use of hos-

pital facilities, and, in the absence of sound statistics, the expense of numerous contract revisions. Follmann reported that the Health Insurance Association of America, with the American Dental Association, has been developing a statistical base for estimating costs.

He suggested that a workable plan would protect against costly dental care in or out of the hospital, within the frame of comprehensive medical cost insurance, leaving the less expensive and the luxury items to be borne by the individual. For workers in industry, he proposed examination and referral combined with postpayment for routine costs and insurance for serious and unpredictable expenses.

Outlines the Objectives Of Dental Care Plans

Only 31 percent of the American people who need dental work are getting it, mainly because of cost, in the opinion of Jerry Voorhis, executive secretary of the Group Health Federation of America, Chicago. The solution lies in the group dental health plan, he believes, because of reduced costs resulting from lower overhead, better use of equipment, and fewer expensive operations brought on by neglect.

In illustration, he mentioned the dental care plan of a longshoremen's union, used by 95 percent of the eligible children of members, and a group practice clinic in West Virginia which gives all kinds of dental care to miners who pay \$1 a month. Losses are subsidized by a miners' association. Both dental restorative work and maintenance are supplied in the medical plan of a St. Louis teamsters union, supported by a health and welfare fund to which employers contribute 5 percent of the payroll.

There is still no "magic formula" for restorative work, he commented, describing as practical the plan of Group Health of Washington, D.C., which, on completion of restorative

work, maintains oral health on a prepaid basis.

He pointed out that maintenance costs are predictable, about \$40 to \$50 per year as estimated by a Public Health Service publication in 1954.

Voorhis defined the aim of group dental plans as high quality dental care, including treatment before serious decay, as well as ample compensation for the dentist. Such care is not always possible in solo practice, fee-for-service dentistry, he said, where specialization is difficult, time and equipment are often wasted, and the dentist is sometimes preoccupied with economic problems.

Health Agency Action

The health agency has a heavy responsibility, not just a "role," in the development of group dental care ventures, asserted Dr. Arthur Bushel, director of the bureau of dentistry, New York City Department of Health. He pointed out that the activity is justified as a contribution toward fulfilling unmet dental health needs of the community.

Toward encouraging such enterprises, the agency provides neutral ground for all groups concerned, said Bushel, remarking that many unilateral plans do not "get off the ground" because they are soon opposed by some local group.

The agency can contribute by supplying health statistics for estimates on costs and utilization and on dental manpower. It can also train survey personnel, interpret survey data, and give administrative leadership. Most important, concluded Bushel, the agency's dental health education effort can be directed at the community's potential subscribers.

Health Insurance Plan Offers Social Service

Social work consultation has been added to the services of the Health Insurance Plan of Greater New York, according to Edith S. Alt, di-

and 6 found free of neuropsychiatric disorders.

For the immediate future, Tureen sees an urgent need for the addition of a social worker to the psychiatric service, as well as increased psychiatric staff. He also recommended adding to the regular staff a psychologist who was employed periodically on a fee basis.

Dual Choice Programs Developed in California

A choice between the traditional fee-for-service type of health insurance and a group practice prepayment plan is offered beneficiaries of health and welfare funds by 53 industrial and occupational groups in the San Francisco Bay area, according to Avram Yedidia, consultant to the Kaiser Foundation Health Plan, Oakland, Calif.

Development of such dual choice programs, Yedidia declared, has permitted the Kaiser plan, a group practice plan, to provide medical care to employees covered by health and welfare funds without departing from its principle of voluntary enrollment. The fee-for-service plans in dual choice programs are provided by commercial insurance companies, Blue Cross, or Blue Shield (Blue Cross and Blue Shield are competing organizations in California).

Originally set up for employees of the Kaiser companies, the Kaiser Foundation Health Plan was opened to other groups and individuals at the end of World War II, with voluntary enrollment as a basic concept.

Analysis of Kaiser plan hospital utilization rates for 1957 for dual choice groups indicates that the rates are directly related to age, as are the rates for the total membership of the plan, Yedidia said. He concluded that "the mechanism of dual choice does not appear to result in favorable risks selecting one plan and unfavorable risks selecting the other."

Yedidia noted, however, that special circumstances in a group may produce substantially different types of enrollment in the two types of plans. He pointed out also that when dual choice is introduced to a group which already has a prepayment plan, the existing plan has the decided advantage, at least as far as numbers are concerned. Furthermore, few individuals shift from one plan to the other, although the opportunity once each year to change is a feature of the dual choice programs.

Migrant Worker Contracts Include Health Insurance

Nonoccupational health insurance is provided for certain agricultural migrant workers in this country, at the workers' expense. Helen L. Johnston of the Public Health Service described this development in health insurance, which she said is unique in three respects: the character of the groups insured, the auspices under which the insurance is arranged, and the arrangements themselves.

Three groups of migrants are receiving the benefit: Puerto Ricans who come to the mainland under an organized program, British West Indians, and Mexicans. All are single males carefully screened for physical defects and employed under work agreements or contracts, Johnston stated.

For each group, a governmental organization has some responsibility for insurance arrangements. The organization may play an active part in planning the program in addition to selecting the insurance carrier (Puerto Ricans and British West Indians), actually administer the program (British West Indians), or prepare a list of approved insurance companies (Mexicans).

Arrangements for premium collection are essentially the same for each group of workers, according to Johnston. Premium payments

are deducted from the worker's wage by the employer, who sends a single check for all his employees directly to the insurance carrier or to the responsible government agency. The insurance covers only the period of employment. Claims are sent to the same agency as the premiums.

The program for the Mexicans, conducted under an international agreement between Mexico and the United States, differs in one important respect from the other two, Johnston pointed out. For this group, each employer arranges for the insurance with a company selected from among those on a list prepared by the U.S. Department of Labor. For the other two, the insurance carrier is selected by the government agency on the basis of bids submitted each year.

District Dentists Devise Group Service Plan

The District of Columbia Dental Society has established a nonprofit corporation to administer group dental care plans, announced Dr. Steven O. Beebe, chairman of the economics committee of the society.

The corporation is expected to be in operation soon. At present, the District of Columbia, Maryland, and Virginia Boards of Dental Examiners are investigating, at the request of the dental society, the corporation's legality with respect to the dental practice acts.

Steps completed include development of a tentative fee schedule and an estimate of dental needs in a representative group, Beebe reported. These can serve as a basis for estimating service costs, although final determination of the premium must await accumulation of actual experience.

The tentative schedule of fees is based on findings of a survey among dental society members to ascertain their charges for basic treatments. For the estimate of dental needs, one-fifth of the members of an in-

Frequency of medical visits for preventive health services was high among children and prospective mothers, but it tapered off almost to nothing for adults, especially the older ones, the authors reported.

Changes Seen

The authors suggested that the numerous social groups in the county could be put to use in increasing health consciousness and in deciding how to carry out the many nursing and home sanitation activities that are clearly needed in the county.

They concluded that meeting the needs of differing counties may entail changes in the role of public health personnel in the community, new ways of financing health services, and new combinations of skills, and, above all, it may entail "giving up our dedication to established notions of exactly how health services should be delivered."

Finds Method to Slim Experts' Waste Line

A new method for evaluating and making more effective use of the time and talents of professional public health personnel was described by Harvey L. Shapiro, assistant to the executive vice president, Albert Einstein Medical Center, Philadelphia.

Pointing to an already critical shortage of well-trained and well-qualified personnel, Shapiro said that professionals presently employed in nonclinical positions may be wasting more than 50 percent of their time in nonprofessional activities.

A professional activity, he explained, is not an activity which a professional performs or is asked to perform; it is an activity that requires professional training and experience, and simply cannot be performed by one with lesser, or other, training and experience.

Shapiro suggested how health program directors can develop with

their staffs a workload study form which would permit them to analyze the kind of jobs they do and time spent on them. Representative periods on the job should then be selected for study, with, perhaps, a 1-day pretest of the form.

After sufficient data have been collected, Shapiro observed, the percentage of the time spent on each class of activities is easily calculated as a proportion of the total elapsed time for the selected period; spot checks should be used to verify calculations. Following an analysis of the results in terms of specific program objectives, a rescheduling of functions emphasis based on program need should be undertaken, he said.

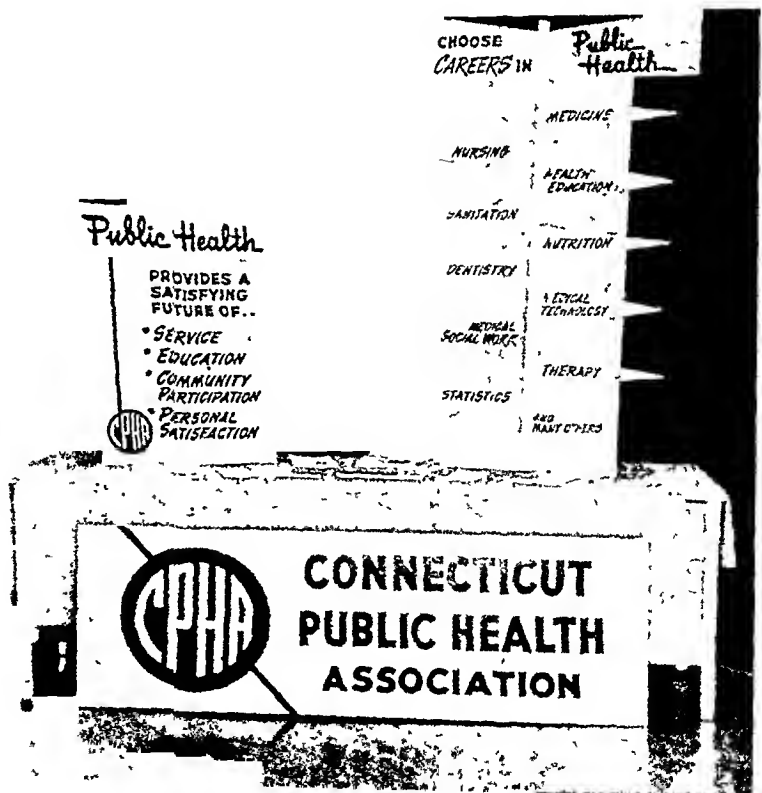

In the example of his method, Shapiro showed that a medical social consultant spent 45 percent of

her time on nonprofessional activities such as typing, filing, arranging for transportation, and preparing weekly statistical reports, all of which, he said, could have been done by a skilled nonprofessional.

Released from tasks of this nature, Shapiro said, the medical social consultant could have spent more time in the activities for which she was trained, or she could have taken on additional duties for which she, by training and experience, was fitted.

Promotes Student Interest In Health Careers

To stimulate the interest of Connecticut's junior and senior high school students, the Connecticut Pub-

"Health Careers" recruitment exhibit.

rector of the community resource division, which administers the program. The program has, in addition to the director, four consultants in the field, each assigned to one borough.

The three main objectives, Alt said, are to provide direct service for HIIP's subscribers, to provide consultation service on community resources and social services to physicians and other personnel in the 33 medical groups of HIIP, and to participate in all types of educational activities.

Direct service activities are planned not only to help with social and psychological needs of individu-

als referred by the medical groups but also to help the referring physicians learn more about the subscriber's problems. Only through the experience resulting from individual referrals, Alt declared, do we expect to modify attitudes and feelings sufficiently to affect a broader segment of the subscriber population.

In setting up the program, it was necessary to evolve practical methods through experience, for there was no blueprint to follow, Alt remarked. She believes the present program will help to demonstrate the possibilities of social work in a voluntary prepayment plan.

and, conversely, health action may sometimes be determined by motives unrelated to health.

Traditional Health Services Need Reappraising

Are current public health practices fitted to deal with current public health problems? This question was posed by four investigators from the Bureau of State Services, Public Health Service: Dr. Donald Harting, Dr. Gordon Macgregor, Dr. Barker S. Sanders, and Dr. Irwin M. Rosenstock.

For their initial study, designed to explore the implications of their query, the investigators chose Kit Carson County in the Great Plains of Colorado: 2,160 square miles, with only 6,700 people. The aged, 65 or more years, are relatively numerous. Infants under 1 year are relatively few, as are young people, aged 15 to 35.

Survey Results

A morbidity survey revealed, the authors said, that the major health problems in the county were heart disease, asthma, hay fever, and other allergies, diseases of the genitourinary tract, arthritis, back trouble, and other troubles interfering with motor function.

But, the authors found, no local organizations were providing such services or skills as physical or occupational therapy to prevent or ameliorate some of these conditions. Instead, one frequent procedure was recourse to a chiropractor. For men 45-54 years of age, the volume of service was actually greater for chiropractors than for physicians.

The dominant social value among these people, the authors observed, was independence; they frowned upon accepting help without paying for it in money or in kind. Beyond the public sharing of the costs of public health service, the authors asked, cannot the user of a service pay his share, to avoid the appellation of charity?

Methods and Management . . .

Puppeteer Questions The Dramaturgist

Shall the person interested in stimulating people to give highest priority to health matters alter his program to appeal to people's needs or shall he try to teach people new motives for health? asked Dr. Irwin M. Rosenstock, chief, Behavioral Studies Section, Public Health Service.

Adapting programs to people, Rosenstock said, might require radical reorganization of present programs and administration in order to use strongly held economic, sexual, or parental motives. On the other hand, he said, teaching new health motives to people might conflict with other strong values they currently hold.

At the present time, Rosenstock pointed out, there is not enough knowledge of people's motives and beliefs concerning health action to provide a wholly scientific approach to improving their health behavior. Additional research will be needed to permit a more scientific approach. However, he added, much can be done currently to increase public participation in health programs by using the results of past research.

The reported conclusions grow out of a consideration of principles of human motivation which apply to health action. According to Rosenstock, they are:

1. Behavior is determined first by the degree to which a person sees a health problem as threatening, that is, having both serious consequences and a high probability of occurring in his case, and second, by the extent to which the motivated individual believes that some course of action open to him will be effective in reducing the threat.

2. Behavior emerges from conflict among motives and among courses of action. When motives conflict and compete for attention, those with the highest value for the individual will be aroused. The motive for health, at least in the person who believes himself healthy, is probably not as potent as are economic and social motives. When an individual believes that no available course of action will be effective or that a prescribed course of action will create equally or more serious difficulties of other kinds, he is the more likely to follow a false course.

3. Motives related to health may not always lead to health action,

1. Long-term studies were undertaken as the need for them was envisioned.

2. Accumulated family records in Hagerstown, where the population remained highly stable, enabled researchers to analyze the effects of changed economic conditions on growth and development; relate Selective Service findings to the physical condition of men examined when they were children; study the relationship of chronic illness and economic status over a 20-year interval; provide long-term data on the progressive effects of illness; standardize techniques for health examinations and casefinding; and compare cardiometric examinations over a 20-year interval.

3. The decayed, missing, and filled index of dental health originated in Washington County.

4. Studies were completed on vitamin A deficiency, hearing acuity, and the effects of repeated inoculations with pneumococcus antigen.

5. Data collected in this area have been widely used for comparison with findings in other health studies, for planning health programs, and for instruction in schools of hygiene.

6. Participation in research by members of the health department's staff has increased performance, competence, understanding, and enthusiasm. Research opportunities have, in addition, attracted persons with high qualifications.

7. Research activities have enhanced the interest of the community in services to health.

Medical Students Ignore Public Health Careers

Only 5 percent of 2,669 medical students in 8 schools signified agreement with the statement, "I am considering making public health my major field of interest."

Factors influencing the recruitment of physicians to work in public health are under investigation by the committee on professional edu-

cation of the American Public Health Association. The authors of this particular study, all from the University of North Carolina School of Public Health in Chapel Hill, were Drs. Robert E. Coker, Jr., Kurt W. Back, Thomas G. Donnelly, Norman Miller, and Bernard S. Phillips.

Terming the reply "not surprising," the authors went on to examine the attitudes underlying the highly negative response. Other questions revealed, they said, that there was considerable confusion, even among those students expressing interest in public health, as to what the public health field comprises.

Although medical students who want to specialize in public health are relatively few, 21 percent of the students said they were interested in doing some work in public health as part of a different career, the authors said.

"The general picture we get from those interested in public health," the investigators reported, "is that they are less clear in their thinking than other medical students about their future as physicians. This apparently is the impression which they give to other students, who characterize them as less ambitious, less independent, and less creative, and this stereotype represents approximately the picture these students give of themselves."

Attitudes Differ

The students favorably disposed to public health differed from the others in that they were considerably less interested in independence of action, in a variety of activities, or in certainty of effect. They were also less concerned with prestige within the profession, with a manageable workload, and with challenges to their capabilities. They were less concerned with serious consequences in the event of mistakes and with having a job which would require exacting analysis, cast them in the role of counselors, or provide a high income, the authors found.

On the other hand, they said, stu-

dents favorably disposed toward public health were more likely to feel that an ideal job should permit a contribution to knowledge. Another finding was that, given a choice among independence, success, and popularity, students favorable to public health put success last; among students negative to public health, success was the first choice.

The authors added that the favorably disposed students were less likely to have been premedical students in college and were more likely to feel insecure about their standing in medical school.

Backgrounds Differ

The background of the 21 percent favorable in some way to public health was revealing, the authors stated. These students were found to have less financial backing for their future plans as physicians, and were more likely to come from professional families, other than medical, which emphasized satisfactory occupation rather than a financially rewarding career.

Furthermore, these students revealed stronger religious convictions than those negative to public health, which the authors thought was likely to play an important role in their motivations.

Describing the situation for public health as "bleak," the authors pointed to two rays of hope. First, there are some medical students who manifest some interest in public health, and this interest might be nurtured and exploited. Second, current choices among medical students are frequently not final, and, moreover, public health physicians are usually late in making their ultimate career commitments.

Emergency Planning Needs Cited

Far too little is being done by health services to prepare for disasters, according to the American Public Health Association's committee on emergency sanitation prac-

lic Health Association organized its own committee on public health careers in 1956.

The chairman of the committee, Dr. Henry Eisenberg, internist with the Connecticut State Department of Health, reported on its activities.

The committee has coordinated recruitment efforts with those of the Connecticut League for Nursing, the Connecticut Health League, and the Connecticut State Medical Society and its affiliates.

In the last 2 years, Eisenberg said, the committee has assigned speakers for scheduled talks before students, distributed literature and films to guidance counselors, started free membership for students in the Connecticut Public Health Association, participated in "cluster career days" of the junior chamber of commerce in Hartford, and displayed an exhibit at many meetings of professional health organizations and guidance counselors (see illustration).

A guidebook on public health careers has also been prepared and should be ready for distribution sometime in 1959, Eisenberg said. The guidebook, written for junior high school students, describes public health careers, academic and personal qualifications, salary range and place employed, accredited schools where training may be obtained, scholarships and loans, and further sources of information.

Health Departments

Expand Research

Among several encouraging indications of advance in research is the fact that new Public Health Service extramural research projects have jumped in number from an average of 10 a year to nearly 30 during fiscal year 1957. The number of health departments participating in these grants has increased proportionately.

Summing up the role of the Public Health Service in research was

Dr. W. F. Mayes, assistant chief, Division of General Health Services, Public Health Service.

In the Service's extramural research grant program, he noted nearly \$1 million has been allocated in the past 12 years to support research in State and local health departments and one-fourth of that sum was granted in fiscal year 1957.

As an example of its intramural research activities, the relative amount of the total operating budget of the Bureau of State Services helug allocated for research has increased from 30 to 50 percent between 1952 and 1958, Mayes said.

Other actions taken recently by the Service in response to the growing interest in research are, Mayes said:

- Creation of the key position of medical director, Community Services Program, in the Office of the Director, National Institutes of Health.

- Division of the old Public Health Study Section into three study sections: Nursing Research, Sanitary Engineering and Occupational Health, and Public Health Research.

- Division of the Mental Health Study Section into two sections, one on mental health and the other on the behavioral sciences.

- Establishment of general and specific research training grants and fellowships.

- Making available sizable grants for the support of experimentation and demonstration in new community mental health programs.

- Setting up a special advisory committee on epidemiology and biometry, with training grants in these subjects available to the schools of public health.

- Setting aside a portion of the Hill-Burton Act funds for research and demonstration in the field of hospital and medical facilities.

- Setting up a position of liaison officer for research between the Bureau of State Services and the National Institutes of Health.

- Employment of research grants officers in the Bureau of State Services and Bureau of Medical Services

for the encouragement of extramural research in specific subjects, such as sanitary engineering, nursing, occupational health, air pollution, accident prevention, public health practice, and others.

Reviews Hagerstown Research Record

Research by the Washington County Health Department, Hagerstown, Md., in cooperation with the Public Health Service and the Maryland State Health Department was described by Dr. W. Ross Cameron, deputy State and county health officer for Washington County.

The county was selected for study initially in 1921 because of its relatively stable population and because it was typical of communities in the eastern United States in demographic characteristics, Cameron said. The objective at that time, he observed, was to obtain data on morbidity. The county was used also to test the validity of a number of public health methods.

Early Gains

Publications, especially those on morbidity, originating from the first study period (1921-24) have become standard references, Cameron averred. Furthermore, he asserted, many of the procedures developed during this period are in frequent use today. Patterns were established which nationwide studies have since utilized, including the investigations of the Committee on the Costs of Medical Care from 1926 to 1928, the National Health Survey in 1935 and 1936, and the current National Health Survey, he said.

Later Gains

Beginning in 1933, the studies, which had been concerned with communicable diseases, explored etiological factors for preventing chronic disease. Cameron summarized the accomplishments in research during this period as follows:

tices. Most serious, the committee reported, are the lack of operational planning and the minimal participation in planning for survival.

As an essential element in dealing with disasters, the committee observed, "Operational plans spell out who is boss and who takes the boss' place when the boss isn't there . . . what equipment and supplies are available and where they are to be found, procedures for obtaining transportation, how to communicate, what to communicate, and with whom. The history of disasters is replete with scenes of chaos due to the lack of operational plans that provide for control and direction of the forces offering help, a plan that provides for a description of the course of action to be taken in a contingency, an instrument that provides direction when [conventional] communications fail and becomes the sole guide of individuals until communications and control can be reestablished."

Important considerations and principles relative to emergency planning, the committee said, are:

1. Planning must be established as a basic responsibility and continuing function of all agencies and organizations promoting and safeguarding the health and welfare of the people.

2. Operational plans for emergency sanitation services should be developed by and built around government health agencies at all levels. The personnel of these agencies must provide the framework into which other professional and technical personnel can be integrated.

3. Professional and technical personnel with experience and training in sanitation should participate only in emergency sanitation operation, avoiding responsibilities in other emergency activities.

4. Operational plans for emergency sanitation services should be integrated into the total civil defense and disaster preparedness plan, if it is underway; otherwise, sanitation plans should be developed separately and later integrated into the master plan.

5. Emergency planning must be on a disaster area basis and not restricted to jurisdictional boundaries.

6. Emergency plans must be flexible enough to meet any contingency, regardless of kind or magnitude.

7. Emergency plans must be developed for all areas of the country. Since 1953, only seven States have been free of disasters for which aid was sought from the Office of Civil and Defense Mobilization (see table). In civil defense disasters, planned or spontaneous evacuation of people from disaster areas will impose emergency conditions upon reception areas, which must be met adequately. Areas not affected by disaster or reception conditions must plan to extend assistance and support to affected areas.

8. Training in emergency sanitation practices should be developed and made available to sanitation personnel and auxiliaries. Training should include the use of radiological monitoring equipment to determine the safety of the environment, water, milk, and food, and the use of emergency equipment such as portable water purification units. (In this connection, the committee recommends reinstituting the course given by the Public Health Service prior to July 1957, entitled, "Sanitary Engineering Practices in Civil Defense Disasters.")

9. Continuing research is needed in the development and refinement of procedures for rapid identification of biological organisms.

10. Greater use and familiarity with the molecular filter technique for isolating and identifying bacteria should be promoted among professional sanitarians.

11. All available resources and equipment should be appraised. Needed resources and equipment should be determined; and mutual aid arrangements should be established among organizations to supplement resources on short notice. Lists should be compiled for local use and for State and Federal agencies in planning. Essential emergency items should be stockpiled; many of these can and should

be obtained through OCDM on a 50 percent matching basis.

12. More attention must be paid to potentially disastrous effects of breakdowns of sanitary facilities.

13. Skilled manpower should be developed as auxiliaries to public health workers.

14. In time of disaster, the chief of emergency sanitation services should devote himself solely to the administrative and executive duties of his office, according to the disaster plan.

What Are You Measuring When You Measure?

The number of times that a health officer visits a dairy farm is not a measure of the farm's sanitation practices; neither is the absence of outbreaks of foodborne diseases necessarily an indication that restaurants are following good sanitary methods, commented Dr. V. A. Getting, professor of public health practice at the University of Michigan School of Public Health.

A number of distinctions, he said, are required in the proper evaluation of programs or procedures: distinctions between results and efforts, between objective and subjective criteria, between costs and the merits of certain expenditures, and so on.

The fundamental necessity in proper evaluation, Getting pointed out, is to define one's objectives so that one may further define the attainment of these objectives, measure the degree of progress toward attainment, and evaluate periodicaly the effectiveness of activities.

Getting termed the routinization of certain procedures a "trap." Routine investigations of dairy or restaurant sanitation, after several years and after educational programs have been completed, may accomplish little and that little at an unjustifiable cost, he said. "Merely because a director some 20 years ago started a certain routine procedure and it was found to be good and effective at that time does not mean

¹ Formerly the Federal Civil Defense Administration. Many more disasters occurred than are listed here, but records were not kept of all of them.

² No records for seven States: Arizona, Delaware, Nebraska, Utah, Vermont, Wisconsin, and Wyoming.

³ Rounded to the nearest thousand. The amounts of money allocated by the President serve as a rough comparison of the relative magnitude of the disasters.

More specifically, they indicate the relative damage to publicly owned facilities.

⁴ A portion of these funds were made available to other Federal agencies.

⁵ Alaska authorized to expend unused funds from Presidential allocation of October 30, 1953.

⁶ Presidential allocation subsequently reduced.

⁷ Presidential allocation subsequently withdrawn.

department. But in communities of fewer than 100,000 people, Magnuson said, such activities may be undertaken by the basic health department staff.

Yardsticks Offered

Magnuson suggested several yardsticks with which the health officer might measure the strengths and weaknesses in his own occupational health situation.

In appraising that situation, the health officer should determine the general health status of workers and the specific occupational health problems in his community. He should look for substances that produce dermatitis, chemical causes of toxicity, and environmental factors such as fumes, dust, and noise.

He also thought that the health officer should determine the characteristics of the community's labor force (obtaining such information from the Bureau of the Census, State employment offices, bureaus of economic research, and the local chamber of commerce), and the types of industry in which the workers are employed. The health officer can expect, for example, Magnuson said, a frequency of accidents 2½ times higher in small plants than in large ones. But, he noted, few of the large plants will have medical departments or industrial hygiene services.

When new industries enter a community, he pointed out, the health officer has the opportunity to develop excellent relationships with management and workers by making his services known. Even when a plant is in the blueprint stage, the health officer can be invaluable in pointing out needed industrial hygiene controls, Magnuson said.

Another essential, Magnuson observed, is information on the local incidence of occupational disease. As a first step, the health officer should determine the existence of any laws or regulations requiring reporting of occupational diseases by physicians.

If reporting is required, the health officer should arrange to be

notified of reports originating in his jurisdiction. In this regard, Magnuson said, the health officer can do much to encourage physicians to comply with laws pertaining to the reporting of occupational diseases, and he can encourage reporting by offering assistance in any epidemiological investigations that may be required. Complaints of workers or of persons living in the vicinity of an industry may also be a source of information, pointing to situations that require correction, he said.

Using the Staff

But how, Magnuson asked, can the local health officer undertake these responsibilities without diluting his staff's present activities?

He pointed out that nurses and sanitarians offer the greatest numerical potential for extending services to industry. The public health nurse, who has unquestionably won the respect of industry, can, on routine visits, familiarize plant nurses with community health services, follow infectious disease cases, and demonstrate the values of part-time nursing services in small plants lacking such services.

The sanitarian can extend his usual services of inspecting plant cafeterias, sanitary facilities, and general housekeeping to apply to industrial waste, cross connections, and water facilities. He can help reduce occupational dermatitis by determining that washing facilities are adequate and are used effectively. With some training, he can locate trouble spots for action by specialists, see that recommendations are complied with, and assist in surveys of environmental conditions in plants and in industrial health programs.

When the health officer encounters situations requiring specialized help, he can avail himself of his State health department services, as well as those of other local health departments, insurance carriers, voluntary agencies, professional associations, universities, and private consultants, Magnuson said.

He called attention to a kit containing detailed information on occupational health which is available from the Public Health Service's Occupational Health Program.

Magnuson concluded that the occupational health field may be one of the most effective for multiplying the resources of the health department in bringing services to people.

Aesculapius Cures Own Headache

Attempts to persuade industry of the need of industrial hygiene backfired when industry asked why the State government did not provide health services for its own employees, related Dr. Lester M. Petrie, director of the preventable diseases service, Georgia Department of Public Health.

As a result of rebuffs like these, Petrie said, the Georgia State Employees' Health Service was begun 3 years ago. Its policies were approved by the State and local medical societies and by the Georgia Association of Local Public Health Physicians.

The primary objectives of the employees' health service is to teach the State government's 24,000 employees the responsibility of each individual for his own health, the limitations of his own resources, and the community resources available to help him, Petrie said. With 20 people a day, 80 a week, and 3,000 by the end of the first year reached, Petrie called it "mass education."

Educational Means

Petrie said that the educational program uses multiphasic health screening tests, counseling in health problems, and first aid and emergency service.

The multiphasic health screening procedure consists of an approved battery of health tests offered to each employee on an annual basis; the tests are designed to aid him

that it must be continued at this time or in the future," Gettling said.

The rapidly changing environment requires flexible programs of environmental health and open minds, he said. Progress in environmental health can be attained, he added, if we question accepted practices, investigate new approaches, test new ideas, and set new objectives.

Getting called upon public health workers to make use of the special competences available in schools of public health, and to use standards purposely developed by the American Public Health Association to aid evaluative studies. "The application of these standards to specific programs is evaluation. But to inventory or list activities is to survey a program without adequate measurement of the attainment of objectives," he concluded.

Voluntary Sanitation Pays Dividends

Sanitation in food-handling establishments improved by 18 percent in 12 weeks as the result of a voluntary self-inspection program in Rocky Mount, N.C. Public schools in the city improved the sanitation of their facilities by 16 percent in the first 2 years of a continuing voluntary program.

Commenting on these developments were Kelly G. Vester, senior sanitarian of the Rocky Mount Health Department, and Dr. J. W. R. Norton, State health director, North Carolina State Board of Health.

After the interest of management, food handlers, and the public had been aroused and cultivated, and the press, the local government, and civic groups had endorsed the plan of voluntary inspection, appointments were made in advance at restaurants for inspection during slack periods. This enabled the restaurant staff to observe the complete plant inspection and to rate themselves. In 60 establishments, 500 workers were allocated 1 inspection per month. The inspection program was based

on the North Carolina Restaurant Code and used a questionnaire covering 21 sanitation items.

During inspections, Vester and Norton said, equipment was disassembled and scraped with a knife, and deposits from the surfaces were spread on a napkin. Tables, sinks, pots, storerooms, and hard-to-reach places "went under the knife." The temperature of refrigerators and dish sanitizing equipment was also carefully noted.

The inspection form was read aloud and answers to the questions were determined by a majority staff vote, Vester and Norton reported. Informal roundtable discussion brought numerous sanitary shortcomings to light. Nobody was criticized, they said, and discussions were mutual aid sessions; reactions indicated that everybody intended to do something.

Public school self-inspection in Rocky Mount was launched on a similar basis at the beginning of the 1950-51 school year. Cooperation was obtained from the school superintendent, principals, teachers, students, and the PTA. Equipped with a questionnaire covering the sanitary aspects of the physical plant, toilets, showers, dressing rooms, and outside environs, the program got underway with weekly inspections, Vester and Norton related.

At the beginning of the 1951-52 school year, they said, the schools were graded on existing sanitary conditions. By May 1952 they had showed an improvement of 6.4 percent. The next year a "sanitation hour" was added which included such projects as lighting surveys, room and grade competitions, posters, and essays. By the end of the second year, school sanitation had improved citywide by 16.1 percent. School officials have since accepted the responsibility of carrying on this work, they said.

In another presentation, Charles L. Senn, sanitation director of the Los Angeles City Health Department, compared self-inspection plans with fee-for-service charges, and

pointed out that at present several different inspection agencies cover the same territory with a concomitant duplication in costs.

Inspection by management of its own establishment as a part of regular supervision, he said, is a most desirable form of self-inspection. Utilization of the services of consultants and fieldmen provides a level of service superior to that usually available through an official agency, Senn observed, but he warned that self-inspection is not a satisfactory substitute for periodic official inspections made frequently enough to determine reasonably that proper sanitation is being maintained.

Misconceptions Block Occupational Health

Four misconceptions stunt the local health officer's interest in occupational health, according to Dr. Harold J. Magnuson, chief of the Occupational Health Program, Public Health Service.

First, he said, occupational health still has a limited connotation for many people, who restrict it to mine, mill, and factory. It should be applied to every place people work, including the farm.

Second, many confine occupational health to the identification and control of harmful exposures in the workers' environment. It should be extended to embrace the idea of maintaining the health of the employed. Moreover, Magnuson argued, local health officers should look upon occupational groups as potential action bodies needing help to solve their general health problems.

Third, industry is too often considered separately from the community. As a result, both industry and the health department suffer through a failure in communication, he observed.

The fourth misconception is that an occupational health program must necessarily be a specialized and separate activity of the health

He credited the SSA's Medical Advisory Committee, drawn from medical and allied professions outside the Government, with invaluable assistance in the development and refinement of OASI policies, as well as in the explanation of methods and objectives to the profession.

Retarded Learn to Earn in Hartford Project

More than half of the mentally retarded adults enrolled in a Hartford, Conn., project were trained to earn a living in competitive or sheltered employment, reported Dr. Alfred L. Burgdorf, director, Hartford Health Department, and Alice Moore, coordinator, job training program, Hartford Association for Retarded Children.

Over a 29-month period 46 persons were admitted to the project: 17 demonstrated ability to work in competitive employment; 8 had ability to work in sheltered employment; 11 proved incapable of benefiting from training; and 10 were still in training. The total earnings of those employed are \$23,000; total cost of the program is \$43,500, the authors said.

Trainees were limited to persons 16-35 years of age with I.Q.'s ranging from 50 to 75, who were sponsored by the bureau of vocational rehabilitation, Connecticut Board of Education, and who could travel alone.

The project was initiated in 1956 by two voluntary organizations, the Greater Hartford Association for Retarded Children and the Hartford Rehabilitation Center. The center's physical facilities, provided by the city, are located at the site of the city hospital, operated by the welfare department and the health department. Health department staff members are active in both voluntary organizations and confer frequently with the center's staff.

Training Procedures

Medical and psychological examinations, admittance interviews with prospective trainees and their families, and prevocational exploration and appraisal preceded the actual training. The training included placement in the center's industrial workshop and subsequent placement in the city hospital or in an on-the-job training location.

Individual and group counseling, classes in posture training, continuing evaluation and planning, medical review, and group sessions with trainees' parents were held concurrently with training.

According to the authors, the results indicate that retarded persons may be too immature at 16 years for job placement, and that consideration should be given to requiring those with a certain I.Q. to continue

in school to a higher age. I.Q. levels, they found, were not a completely reliable index; the ability to conform to socially acceptable standards of behavior and be socially independent is necessary.

More extensive psychological testing and prevocational exploration and appraisal were needed. Trainees lacked familiarity with actual work situations and had to acquire work habits and skills before they could be transferred to job training.

The city hospital and a super-market proved to be useful on-the-job training locations for those who lacked the dexterity and coordination for factory work.

The authors felt that in a metropolitan area, combined planning and programming by voluntary and official agencies provide services of a caliber neither could produce individually.

Records and Statistics . . .

Hospital Records at Odds With Interview Data

Comparison of hospitalization data obtained in a household interview with data from hospital records reveals marked discrepancies, which increase in magnitude as the comparison becomes more specific, reported Dr. Barkev S. Sanders, medical economist and statistician, Public Health Service.

His major interest in this comparison, Sanders declared, is not as a test of the validity of household survey data on hospital utilization, but rather as a measure of the reliability of other information commonly collected in morbidity surveys. We lack appropriate criteria for direct evaluation of this other information, he pointed out.

Using the hospital records as the basis for appraising the household survey data, the study found an error of 8 percent in number of individuals hospitalized. For number of

days hospitalized, the two sources gave an identical figure for only 53 percent of those hospitalized. For 44 percent of the admissions, the two sources agreed as to number of days, and the total days for these cases accounted for 40 percent of the days of hospitalization shown by the hospital records.

It was observed that if the object is to obtain average measures of hospital admissions, or days of hospital care, or hospital stay per admission, the differences are much less because of the compensatory character of the errors. For example, 19 individuals were reported hospitalized by the household survey but not by the hospital records, while 25 were reported hospitalized by the second source but not by the first.

Perhaps more important for appraisal of morbidity surveys in general, Sanders indicated, the study revealed a host of factors that seem to affect the level of agreement:

and his physician in evaluating his health, Petrie said.

The health service offers no medical care other than first aid, he pointed out, and all employees who are found to have a health problem are urged to see their private physicians, to whom the results of the tests are reported if desired.

The employees' health service differs from the usual industrial medical department in that the latter's services are normally saturated by 10-25 percent of the workers who are repeaters. The employee's health service, Petrie said, tries to reach the other 75 to 90 percent with an educational program designed to keep them healthy. Petrie estimated that 90 percent of those referred to their private physicians would not have gone had it not been for the screening and health education message that went with the tests.

Protocol Cited

A protocol for promoting an occupational health program for local government employees was unanimously approved by the Georgia Association of Local Public Health Physicians in May 1958, Petrie said.

The protocol gives a formula for estimating the financial value of a reduction in sick leave. The health service would only have to reduce sick leave by 0.175 sick leave hour per 100 man-hours worked to offset the cost of the service, Petrie observed.

Preventing illness, Petrie concluded, means maintaining the productive capacity of our labor force and the wealth that is so vitally needed to continue services. For these reasons, he said, no one, especially a health department, can afford to ignore the opportunities of the occupational health approach.

OASI Disability Ineligibles Present New Dilemma

The handicapped citizen who is denied disability benefits but who is nevertheless rejected by prospective

employers as unemployable presents a serious dilemma, declared Arthur E. Hess, assistant director, Division of Disability Operations, Bureau of Old-Age and Survivors Insurance, Social Security Administration.

The situation, he indicated, is the result of two different points of view. On the one hand, the OASI disability program has as its key-stone "medical determinability." Under this concept it must deny disability benefits to handicapped persons who, from a clinical standpoint and in light of their age, education, and personal characteristics, have enough physiological or functional reserve to perform any substantial work.

An employer, on the other hand, even though he may recognize a valid social need, is concerned primarily with what the job candidate can contribute. He may decide that the candidate has "too little capacity for work left to regain his place in the industrial community."

Hess suggested a two-pronged approach to the predicament: One, expand medical and other resources or marshal present resources in such a way that disabled citizens may receive more effectively the advantages of modern medicine and related services. Two, stimulate employers, labor organizations, and community agencies to explore new avenues of productive activity for persons with limited work capacity.

Applicants denied disability benefits admittedly have characteristics that militate against reemployment, Hess said. For example, they are, on the average, 59 years old, an age at which even the nonhandicapped worker has difficulty getting a new job. In addition, they are in relatively poor health, lack skills, and are victims of academic poverty.

These handicapped persons, moreover, have proved poor prospects for vocational rehabilitation, according to Hess. The law requires that all applicants for disability benefits be referred to State vocational rehabilitation services. However, the "vast majority" of those denied benefits, as well as 94 percent of those whose

claims are granted, are not accepted for VR services, he said.

Assessment of an individual's employment prospects, Hess noted, must take into account not only his physical and mental limitations but also the employment opportunities in the community and the capacity of the local VR facilities. Since VR resources are not unlimited, only the best candidates can be accepted.

He believes that new kinds of restorative services may be needed. Those for whom remunerative work is not feasible may nonetheless profit from social or medical services that would make them better able to take care of themselves, he observed. He assigned directly to the community the major responsibility for seeing that handicapped persons do not become "forgotten people populating a no man's land."

Definition of Disability

Explaining further the statutory definition of disability, Hess emphasized that the inability to work refers to the inability to do "any substantial work," not merely the kind of work last engaged in or the kind for which the applicant is most obviously suited.

The definition also makes clear that the disability must be a physical or mental condition that can be determined objectively by medical examinations or tests and that the disability must be the primary cause of the individual's inability to work. Finally, the disability must result from a condition that has persisted for at least 6 months and that can be expected to continue for an indefinite time.

The decision regarding a claimant's eligibility for benefits, Hess pointed out, is based primarily on clinical and laboratory findings. The necessary data are normally presented in the applicant's medical report, but in some instances supplementary information may be obtained in an examination ordered by the social security agency. Under no circumstances is the claimant's physician asked to certify that his patient is "disabled," Hess said.

Borksy and Sagen inferred that the indifferent response by those in the high socioeconomic stratum reflects a lack of interest in any health service not offered by a personal physician.

Health Insurance Data Acclaimed as Sound

The scientific basis of the data on health insurance coverage published annually by the Health Insurance Council justifies their prominence, in the opinion of David Robbins, assistant director of statistical research, Health Insurance Association of America, New York City.

The data are collected in three separate annual surveys and put together by the council staff, Robbins explained.

One survey, conducted by the council itself, obtains data from insurance companies. Another provides data on Blue Cross, Blue Shield, and medical-society-sponsored plans; the national bodies of these groups collect data from each plan and forward the results to the council. The third survey, conducted by the Division of Program Research of the Social Security Administration, reports coverage through independent plans.

For its survey of insurance companies, the Health Insurance Council, in January each year, mails two questionnaires to each company underwriting accident and health insurance, of which there are currently some 700. One questionnaire asks for data on group insurance and the other for data on individual policyholders. Totals for various types of coverage—hospital expenses, surgical expenses, nonsurgical basic medical expenses, major medical expenses—are segmented into persons insured and dependents of insured. The data are also distributed by State.

The response rate for this survey is so high (covering 86 percent of premiums written in 1957), Robbins maintained, that little atten-

tion need be given the possibility of bias. Estimates of persons covered by nonreporting companies are derived from published information.

Of major concern in determining the extent of health insurance coverage is the possibility of counting the same person more than once, Robbins indicated. To measure the amount of duplicate coverage, the council conducts periodic investigations, he said, mentioning the following studies:

- Analysis of 1,000 consecutive applications for insurance and 1,000 consecutive claim applications with 45 of the leading writers of individual accident and health insurance.

- Information from representatives who install and service group contracts in six leading companies whose business represents more than two-thirds of the total group insurance in force.

- Analysis of several thousand hospital admissions in selected areas of the United States.

Duplication factors derived from such studies, Robbins stated, are split on a judgment basis into duplication within the insurance business and duplication between insurance and other coverages. In determining State figures, it is assumed that duplication is higher in States having a higher proportion of the population covered by the particular type of insurance than in States with a lower proportion.

Colleges Plan Curriculums In Vital Records Science

Vital records, which 50 years ago were used mainly in the mass as public health aids, now serve extensively as individual evidentiary documents.

This change was attributed by Dr. A. W. Hedrich, formerly chief of the division of vital records and statistics, Maryland State Department of Health, to social legislation covering, for example, child labor, adoption, school entrance, and social security.

Twenty-two years ago, the Maryland Vital Records Office issued fewer than 2,000 certified copies per year for evidentiary use. In 1957, he said, more than 55,000 copies were demanded.

Hedrich believes that, since the health department is still custodian of these records, it should set up an advisory board to aid in adapting the records system to all major social needs.

Illustrating the growing complexities of records administration, he compared the former simple omission of father's name from the illegitimate child's certificate with current practices which reconcile conflicting interests of child, mother, natural father, and others concerned. Handling of death certificates also frequently demands acumen in psychology, law, and administration.

To train executives to cope with the complex questions arising from the broader social functions of the records, a number of schools of public health have jointly scheduled an exploratory course for the summer of 1959 at the University of Michigan in Ann Arbor. The outcome, Hedrich said, will aid the schools in setting up curriculums leading to a master's degree with a major in the science of registration and recording of vital events.

Operations Research Meshes Alien Data

An operations research philosophy should be adopted in using statistical data to solve administrative problems, according to Dr. W. V. Charter, director of the Medical Statistics Division, Department of the Navy.

A key point in the process is "the meshing" of data from seemingly unrelated reports," he said. As an example, he referred to his division's use of data from three separate reports in determining optimum allocation of medical officers to hospitals: report of beds and patients, outpatient report, and staffing re-

place of residence; age, sex, and marital status; recency of hospitalization, cause for admission, and length of stay; occupation and family income; age, sex, and educational level of respondent; relationship between patient and respondent. Also, the level of agreement varied considerably among interviewers.

Saunders has concluded that there is need for improvement in household surveys, "especially when the object is to establish interrelationships between, for example, income and illness or illness and occupational pursuits or, even more so, when an attempt is made to correlate health status with volume and type of medical service received."

The type of analysis represented by this study, he said, provides clues as to how the quality of information collected in household surveys might be improved. In the meantime, he urged statisticians to consider carefully the purposes for which morbidity surveys are to be used in order to assess permissible tolerance levels.

The study was conducted in a rural county in the Great Plains area, with about 1,100 families participating.

Ma and Pa Give Survey Consistent Answers

Household respondents answering survey questions for the man of the house gave approximately the same replies as the man himself, reported Philip E. Enterline, chief statistician of the Heart Disease Control Program, Public Health Service.

Enterline set up an area probability sample in six counties of North Dakota in 1956 to test the validity of information provided by household respondents in health surveys. An enumeration of the dwelling units in the sample identified 1,886 men 35 years of age and over. One-third of the men were not at home when the interviewers first called. Information on one-half of these,

selected at random, was supplied by household respondents, 93.1 percent of whom were wives of the men. The interviewers revisited the other half until the man could be found at home and interviewed for himself.

Questions were asked about the men's personal characteristics, work history, food habits, cigarette smoking, illness, medical care, health symptoms, and characteristics of parents.

In only three places, Enterline said, were the differences significant at the 0.05 level. Household respondents reported more histories of rheumatic fever for the men than the men reported for themselves. Men reported more histories of stroke for their mothers than the respondents reported. And the men estimated fewer grams of fat in their daily diet than were estimated by the household respondents.

Enterline pointed out that it would be difficult to generalize about the biases in health information provided by household respondents regarding others in the household, because answers probably vary with the characteristics of the respondents and with the disease under consideration. But, he said, for the type of questions used in the North Dakota health survey, the replies of household respondents will probably result in no less disease reported in total and in broad disease categories than would be the case if each adult were interviewed for himself.

They Wouldn't Say No They Didn't Say Yes

Free health examinations appeal less to old people than to those in any other age group, reported Paul N. Borsky, senior study director, National Opinion Research Center, University of Chicago, and Dr. Oswald K. Sagen, chief, special studies, U.S. National Health Survey, Public Health Service.

The reluctance of old people to

commit themselves to an appointment for an examination following household interviews was revealed by a sample of persons interviewed by the National Health Survey. These people were offered a free health examination and at a later date were reinterviewed to determine why they accepted or refused or if they had changed their minds.

Borsky and Sagen said that those who refused health examinations at both interviews were relatively well satisfied with their health and the status of medical research, reported fewer chronic illnesses, and considered it less important to assist this study by cooperating. Relatively few, the authors related, expressed any desire to see a doctor or thought that their illness would impose a difficult financial burden on their families. From their reading, radio, and television habits, it was apparent they were relatively disinterested in health matters. They also had less faith in doctors, tended to diagnose their own complaints, and had higher incomes than those who agreed to come for free examinations.

Those who refused an examination after having agreed to have one reflected many of the attitudes of those who persistently refused. Their interest and concern about health matters, however, was lower, and they tended to be concentrated at the two extremes of age, income, and education, Borsky and Sagen said.

The authors explained the change from refusal to acceptance resulted primarily from accepting a proxy answer for someone absent at the first interview.

Those who cooperated consistently with the survey, Borsky and Sagen observed, generally take their health and the consequences of illness seriously, believe that research should be supported and improved, come from the middle group of age, income, and education, report more chronic illnesses, and have confidence in their physicians. They include a relatively high proportion of nonwhites.

Medical and Nursing Care . . .

Health Service Coordination s Theme of Administrator

From a world perspective, one cannot help but observe a trend toward more and more socially organized and financed health service, stated Dr. Milton I. Roemer of Cornell University, emphasizing that this is an observation, not an advocacy. If valid, this observation means, he said, that the need for health service coordination at the local level will become more and more manifest, both to the technicians and to the public.

Roemer, director of research at the Sloan Institute of Hospital Administration, strongly supports "unified health administration in general and health department participation in medical care programs in particular." He believes that such arrangements are most likely to incorporate prevention into day-to-day medical care administration and to give appropriate emphasis to the various health needs.

Also, Roemer maintained, unified administration can permit use of the highest caliber administrative skill at the lowest total cost; it can strengthen the competitive position of health services in the arena of government and in the larger arena of total national goods and services that must be financed; and, most important, it allows individuals to be served as whole persons.

Four Administrative Patterns

In examining health service organization, with particular attention to relationships between public health and medical care administration, Roemer grouped countries into four categories, according to their predominant administrative pattern: free enterprise, social insurance, public assistance, and universal service.

In the free enterprise system, which is predominant in the United States, Canada, and Australia, the

health department, particularly the local agency, tends to concentrate heavily or exclusively on administration of preventive services, Roemer said. Health insurance is administered mainly by voluntary societies; general hospitals are usually controlled by local voluntary groups; and health centers are ordinarily buildings for housing health departments, rather than places for ambulatory health care.

Countries of western continental Europe, Japan, and Israel provide most medical and hospital services for most of the population through social insurance systems. Physicians giving home and office care remain in private practice and receive fees from the insurance funds, but hospitals are predominantly governmental, under local or provincial authorities, with most medical personnel employed by the hospital administration. (Israel, with its salaried insurance physicians in health centers, is exceptional.)

Under the social insurance pattern, Roemer pointed out, the health department has little connection with administration of the health insurance funds, which are usually supervised by the ministry of labor or of social welfare. Some social insurance institutions have started their own preventive service, while in Scandinavia salaried district health officers provide medical care for the rural population.

Hospitals come under much greater public health supervision where social insurance of medical care applies, Roemer observed. Typically, he said, the health ministry has a division for hospital supervision, and the provincial health officer is responsible for operation of all public hospitals in his area.

The public assistance pattern is found principally in Asia, Africa, and Latin America, stated Roemer. For the majority (but not all) of the population, medical services are provided free by the government and financed from general revenues.

Most of the services are given by salaried personnel working in hospitals, dispensaries, or health centers.

The administrative pattern in these countries, Roemer continued, vests wide authority in the health department. The national health ministry is ordinarily responsible for all curative as well as preventive services; the provincial and district health agencies usually administer the hospitals and also provide ambulatory medical care.

For the relatively small middle and upper classes in the cities there are private hospitals and private physicians, Roemer observed. He noted also, that the health insurance idea has recently been spreading in Latin America, particularly in Chile, where 70 percent of the population is now covered.

The Soviet Union and other communist countries, Great Britain, and New Zealand were classed as universal service countries. Virtually complete medical care is provided as a public benefit for all persons. Almost all hospitals are owned and operated by the central government; almost all personnel are under contract with the government and are paid with funds derived mainly from general revenues.

In the Soviet Union's scheme, Roemer reported, the health ministry has authority over all preventive and curative health services, and all personnel are on full-time salary.

In Great Britain and New Zealand, the focus of authority in the health department is less sweeping. At the national level, the ministry of health does indeed, Roemer stated, have full authority, but at lower levels, other bodies than the health department have responsibilities. Hospitals and specialty services are administered by regional boards, and ambulatory care, by local executive councils, both of which are responsible to the national health ministry. The local health departments provide traditional preventive services, along with certain auxiliary curative functions.

Significantly, Roemer said, the need for coordination of all these

port. Each is submitted in order to measure a different aspect of the Navy's medical program. By relating the data something new is produced, he said, something not originally intended when the reporting system was set up.

To illustrate how statistics can serve as a tool for managerial control, Charter described in detail the procedures his division follows in estimating requirements for medical officers for hospitals. The objective, he pointed out, is realistic requirements, within the limits of personnel ceilings and other practical considerations, not what would be desirable under ideal circumstances.

Physician-patient ratios for each of several categories of patients have been developed, and each quarter these are applied to the reported workload of each hospital. To avoid a purely mechanical approach, however, individual situations are always considered, he remarked.

The estimates, Charter claimed, are "a good starting point and a good basic tool for physician allocation." He listed the following three ways in which they can be used:

- As a means of comparing hospitals to see whether any are relatively understaffed or overstaffed.
- As a measure of the validity of requests for personnel increases sent in by the hospitals.
- As a guide to allocation of medical officers when the total number of personnel is increased or decreased.

The value of our functions lies in obtaining current data, making systematic computations and evaluations, and presenting the data and statistical analyses in meaningful terms, Charter concluded.

Review Tightens Reports On Obstetrical Needs

Ways to produce reliable reporting of pregnancy and neonatal facts were defined by Dr. Samuel Shwartz, chief of the community standards

division, bureau of maternal and child health, and Howard West, chief of the biostatistics and health education division, District of Columbia Department of Public Health.

Since 1940 in the District of Columbia a medical supplement to the birth certificate has carried such data, they explained. After a study in 1952, these changes were made:

- The questions, attached to the face of the certificate, appear in check-box design. They can be answered within 2 or 3 minutes.
- The items deal with subjects the physician can answer readily. They call for factual rather than judgmental responses. There are no items for which short answers are not meaningful.
- There is a periodic review of reporting by individual hospitals. Those institutions consistently reporting poorly are notified and later visited to iron out flaws in procedures. Items answered poorly by most hospitals are reviewed for reconstruction.

• For birth certificates of doubtful character, a form letter is sent to the hospital of birth asking a recheck of data. Also, information on a sample of birth certificates is matched periodically with data in corresponding hospital records.

Interpretation of the data for identifying unmet needs is still in an exploratory stage, they said. It is already clear, however, that the neonatal mortality for live births in which mothers received no prenatal care was about $2\frac{1}{2}$ times as great as for all live births. Low economic status was not a factor, since similar proportions were found in figures from a municipal hospital limited to the medically indigent.

Prematurity, rather than complications of pregnancy, was the major factor in neonatal deaths where prenatal care was lacking, they found. Of all mothers with neonatal deaths, 41 percent had pregnancy complications. But among such mothers who had no prenatal care, only 23 percent had pregnancy complications.

Values Human Judgment Above Punchcard System

Punchcard evaluation systems are highly useful, but they are no substitute for personal judgment, commented three members of the Philadelphia Department of Public Health.

P. W. Purdom, director, and Dr. Morris A. Shiffman, chief of milk and food, division of environmental health, and Dr. F. Herbert Colwell, director of the office of statistics and research, made this remark in connection with an evaluation of their activities in food sanitation.

They offered two general observations on evaluation. First, no method of evaluation will serve all purposes, and second, there is a tendency to produce more data, tables, and charts than can be analyzed, obscuring thereby the important facts.

In accord with these observations, they have developed three evaluative systems using routine records, time studies for personnel in the field, and sampling studies of fieldwork. In addition, they said, they have reduced and simplified the procedures of collecting data. For example, they pointed out, a punchcard for each inspection is unnecessary; a random sample is sufficiently accurate for evaluation and reduces the processing of data by 80 to 90 percent. Furthermore, they found that comparisons of data on an annual basis showed trends more reliably than comparisons on a monthly basis.

The value of coding all time spent on field visits, they said, lies in the accuracy with which unit and program costs are determined for budgetary purposes and personnel productivity for management purposes. But, they cautioned, time measures effort, not accomplishment.

They also observed that it is impractical to evaluate some activities. For example, a pure food education campaign cost \$5,000. A scientific evaluation of the campaign's effectiveness would have cost \$35,000.

certified specialist, not one had a clear understanding of the medical diagnosis and three were incorrectly diagnosed as neurotics, Koplin and his colleagues stated. The group of experts conducting the study concluded that the multiple hospital admissions were related to socioeconomic difficulties and to the lack of a satisfactory patient-physician relationship.

The medical care plan of the UMWFA Welfare and Retirement Fund provides hospitalization, medical and surgical care during hospitalization, and office care by specialists. Actually, with an average of only 1.9 admissions per person in a 5-year period, multiple hospital admissions appear to be a small problem among Alabama beneficiaries, they remarked.

At present, a patient being admitted to the hospital for the third time in 12 months or the tenth time in 5 years is a candidate for referral to a managing physician. To date about 350 such multiple admission cases have been selected for review, and 300 of the patients have been referred.

A basic feature of the managing physician service is the generous amount of time the physician spends with each patient. About 2 hours is set aside for the first visit, of which 60 to 70 minutes is spent in conference. The physician seeks to determine not only the patient's symptoms but his opinions or feelings about his symptoms. He strives to maintain an attitude of sincerity, respect, sympathy, and objectivity. Above all, the conversation is unhurried, and the physician avoids emotional reactions.

Following the conference, the patient receives a complete physical examination and indicated X-rays, consultations, and laboratory tests, and during this same visit, he is given a preliminary summary of the findings. At the end of the visit, the patient is promised continued care and given an appointment to return for a review of progress.

Three physicians serve as managing physicians. They are in prac-

tice by themselves, but are able, to obtain consultations, X-rays, and laboratory tests easily and quickly because they are located in a building in which there is a clinical laboratory.

The apparent success of the managing physician service, Koplin and his associates said, suggests the need for further investigation of the influence of the scope and quality of medical service on multiple admissions and other hospital utilization problems. He would like to see a study, for example, of a managing physician service combined with comprehensive group practice care.

VD Control Among Youths Rated Priority Job

Public health nurses should give high priority to the venereal disease problem in family and school health services, according to E. Alice Clark, chief nurse consultant, Venereal Disease Branch, Communicable Disease Center, Public Health Service.

Her recommendation was based on statistics showing that gonorrhea ranks second and syphilis fourth among notifiable diseases in the United States, and that teen-agers and young adults comprise more than half of the infectious venereal disease victims. She ascribed 50 to 60 percent of these infections to casual relationships and another 25 to 30 percent to steady relationships short of marriage.

Equally disquieting, Clark indicated, are increases in primary and secondary syphilis in 23 States and late latent syphilis in 19 States in 1958, even though there was a decline in all syphilis for the Nation as a whole. She attributed today's latent syphilis to casefinding failure 4 or more years ago. Currently, there are an estimated 1.8 million persons with inadequately treated or undiscovered syphilis, she said.

Pointing to the gap in epidemiology created by a decrease in public diagnostic and treatment fa-

cilities, Clark cited the necessity for health departments to provide epidemiological services for venereal diseases to private physicians similar to those offered for other major communicable diseases. She advised continuous application of control measures with emphasis on casefinding in high-incidence and high-prevalence population groups.

Within this framework, the general nursing service will be called upon more and more to assume responsibility for venereal disease control, she declared. In many agencies the nurses already include venereal disease epidemiology in their work, and in others plans are being developed to integrate venereal disease activities into a comprehensive communicable disease control program.

To carry out such functions, Clark concluded, the nurse must have a sound knowledge of the medical, public health, and epidemiological aspects of venereal disease. She must also understand that the venereal disease patient is an ill person, as much in need of medical and nursing care as the patient with poliomyelitis or tuberculosis.

Ill, Aged, and Disabled Need Homemakers

Illness or disability in a family is the main reason for the need of the services of homemakers, according to a 1958 survey by Maryland Y. Pennell and Lucille M. Smith, Division of Public Health Methods, Public Health Service.

Of 2,188 households in 32 States and the District of Columbia served by homemakers during a 1-week period, the largest proportion, 41.2 percent, were families with children requiring service because of illness in the home. Usually, care was provided for children because the mother was ill, but sometimes illness affected both children and parents.

The second largest group to be helped by a homemaker, 32.0 percent, contained an ill or disabled

activities at the local level is one of the British National Health Service's most pressing needs.

Train Nursing Home Staffs In Rehabilitation Skills

Training in rehabilitation given the staffs of nursing homes in a demonstration project in Illinois benefited approximately 90 percent of the patients, stated John A. Hackley, coordinator, rehabilitation education service, Illinois Public Aid Commission, Peoria.

He reported on the 3-year undertaking, begun in February 1957 and supported primarily by a grant from the Office of Vocational Rehabilitation as well as State and private foundation funds. Generally, 5 percent of the patients indicated potential for referral to vocational rehabilitation, 25 percent were discharged or were pending discharge from nursing homes, and 60 percent increased their ability for self-care and independence within the home in the course of the project. Attending physicians did not feel that 10 percent of the patients could benefit from the rehabilitation services.

The training program was designed to determine the rehabilitation needs of patients, how much can be accomplished by training existing staffs and enlisting the cooperation of local physicians and others in the community, what kind of training will give the staffs knowledge of rehabilitation techniques and a philosophy of physical and vocational rehabilitation, and the kinds of teaching materials that will increase staff competence in rehabilitation, Hackley said.

To participate in the project, nursing homes must join voluntarily, be currently licensed by the Illinois Department of Public Health, have a full-time registered nurse or licensed practical nurse giving nursing supervision, and have patients receiving public assistance. Approximately 20 percent of the State's

eligible nursing homes applied for the rehabilitation training. The two research-demonstration teams have completed work in 24 homes, ranging in size from 17 to 236 beds.

Team Approach

A team consisting of 2 rehabilitation nurses and 1 occupational therapist spends an average of 6 weeks in a nursing home. A daily 1-hour lecture is given for the entire staff; team members devote the remainder of their working hours to demonstrations, return demonstrations, and bedside work with individual staff members.

The team emphasizes the obligation of the nursing home to help define the patient's needs in the home and after discharge. It encourages the administrator or owner to work with agents in the local community to develop resources for comprehensive services to the patient and his family.

Through this approach, the administrator and his staff receive similar training; the staff can translate the training to the kinds of patients they routinely serve; the setting provides additional opportunities for recognizing and dealing with the motivation of the patient; the training team can demonstrate how the philosophy of rehabilitation must permeate every nursing activity; and physicians, who must prescribe rehabilitation for a patient before it begins, receive further interpretation of the nursing home's services.

The nursing home personnel, Hackley observed, developed a new motivation from the improved morale and health of the patients and a change in attitudes that attend improved technical skills. During monthly followup visits by the training team, they were eager to demonstrate gains their work had achieved with newly admitted patients. At first, the nursing home personnel were disappointed at the slowness with which long-term patients responded to rehabilitation services.

Too few administrators and med-

ical personnel appreciate the value of nursing care in rehabilitation, Hackley concluded. Rehabilitation is not the job of the rehabilitation center, the public assistance program, or the health department alone. It demands the coordinated effort of the patient, his family, the physician, public and private agencies, the hospital, nursing home, the day care center, and the sheltered workshop.

The rehabilitation service, which has been designated as a prototype by the Office of Vocational Rehabilitation, will be continued by the Illinois Public Aid Commission after the termination of the grant in December 1959. One State agency is duplicating this service and several other agencies in other States expect to undertake similar training, Hackley reported.

Improved Service Achieved With Managing Physicians

For a group of 76 "multiple hospital admission" patients referred to a managing physician, the annual hospital admission rate has been reduced by 44 percent and the annual rate of hospital days required, by 48 percent, reported Dr. Allen N. Koplin, Richard Hutchison, and Dr. Bruce K. Johnson, all with the United Mine Workers of America Welfare and Retirement Fund, Birmingham, Ala.

The key factor in these reductions is believed to be the definitive medical care and patient satisfaction achieved by the managing physician, they declared.

The managing physician service, in which selected patients are given special attention, was established by the UMWA Welfare and Retirement Fund in the Alabama area in 1956. The action followed a study of 18 patients admitted to hospitals 20 or more times in 4 years. The average number of admissions per patient for this group was 28 and the average number of doctors per patient was 6.

Despite the fact that all 18 patients had been seen by a board

sciences, experience in interviewing and developing interpersonal relationships, knowledge of her area, and community recognition of her functions make the nurse an ideal person to investigate communicable disease cases and outbreaks to find the source of infection and to help in preventing other cases, Lester said. The investigation is an integral part of patient care and family instruction.

Particularly significant are opportunities for strengthening professional relationships. Through

tactful approaches, patient interpretation, and effective service, the nurse can often influence the physician or hospital administrator to appreciate, respect, and utilize the services of the health department, Lester maintained.

Discussing the seriousness of communicable diseases today, she pointed out that they cause 1 of every 12 deaths. Before age 35, they rank second as the cause of death, being responsible for as many fatalities as motor vehicle accidents, cancer, and heart disease combined.

using 2 specially equipped buses, travels to population centers such as State and county fairs to screen groups of people. Chest X-rays, serologic tests for syphilis, blood sugar tests, and measurements of intraocular tension are offered.

Two county hospitals receive funds from the New Jersey State Health Department to employ a physiatrist, medical social worker, physical therapist, and occupational therapist for their restorative treatment units. A study of 188 admissions in one county revealed that the majority of the patients were improved and that many were discharged to return to the community, saving the cost of their maintenance, an estimated \$400,000.

The Hartford (Conn.) Health Department is the medical coordinator in the community's home care program, purchasing from existing agencies the services needed by patients. The Hartford Community Council is custodian of the project funds and coordinator of its non-medical aspects.

Nutritional practices in nursing homes were improved and a nutrition course for home administrators was started as the result of the Milwaukee City Health Department's survey of the food purchases by the homes and the food consumption of selected patients.

Peterson feels that health departments generally are neglecting health education, although they recognize the necessity for exploiting health education for casefinding and patient instruction. He also urged them to do research on the epidemiology of chronic diseases and in administration and program methodology.

Smokers Double Nonsmokers In Heart Disease

"After adjusting for age differences between smokers and nonsmokers, the reported incidence of coronary heart disease was more than twice as high among cigarette

Epidemiology . . .

Chronic Disease Programs Use Familiar Techniques

Chronic disease programs are not new to health departments, and neither are the requisite techniques of casefinding, followup, patient education, and patient services, stated Dr. Paul Q. Peterson, assistant director, National Institute of Allergy and Infectious Diseases, Public Health Service.

Tuberculosis, syphilis, leprosy, and malaria control have long been accepted as proper public health services, and State and local health departments have devoted funds and efforts to chronic disease control activities such as maternal and child health and dental health, he said.

The same administration and management, patient followup, and referral procedures are required for tuberculosis and diabetes. Patient education in chronic disease is based upon the same concept as patient education in maternal and child health. Crippled children's programs, dental health services, bedside care by visiting nurses, all activities familiar to public health, call for the same skills as services to the cerebrovascular accident patient, the arthritic, or the disabled aged, he stated.

Only the specific procedures for the detection of chronic diseases are new. Blood sugar tests in diabetes, tonometry in glaucoma, and cytology in cancer are employed whereas serologic tests are used for syphilis and tuberculin testing and X-rays for tuberculosis.

He attributed the insecurity about chronic disease programs voiced by many in public health and private medicine to recognition of the gross size and complexity of the problem, difficulty in accepting secondary prevention without hope of primary prevention, and resistance to the redirection of standard procedures and staff assignments and to the inclusion of new techniques in program activities.

Successful Programs

Peterson maintained that public health leadership and support are necessary in community chronic disease programs and described five such successful programs.

Chronic disease detection conducted by the District of Columbia Department of Health revealed significant findings in all but a small percentage of 5,000 screened from 1955 to 1958. And this health department's mass blood testing for diabetes identified 1.17 percent of the 96,366 persons tested as diabetic.

In Arizona, a staff of 8 persons,

person of advanced age at home. About one-eighth of such families also had a younger adult ill at home. About one-half of this group of households consisted of single, aged persons living alone.

In 16.7 percent of the households served, care was provided for well children, but the mother was usually absent, either dead or hospitalized. Households with illness of adults under 65 years of age accounted for 10.1 percent of those assisted by a homemaker. In the last instance, the homemaker enabled the patient to remain at home during convalescence or a chronic or terminal illness, Pennell and Smith observed.

The housekeeping tasks most commonly performed by the homemakers were house cleaning; laundry; planning, preparing, and serving meals; and marketing and errands. Activities included sewing and mending, reading aloud or playing games, and even assisting children with schoolwork. On occasion, the homemakers helped a family to move. In practically all families the homemakers gave personal care to children or to ill or aged family members.

For about half the families with persons ill at home, the homemaker provided at least one service directly for the patient. While some agencies encourage the homemaker "to do things for the patient," a few do not permit them to perform any service that involves direct contact with an ill or disabled person, Pennell and Smith reported.

They noted that one-tenth of the families with ill or disabled persons at home were not receiving services from either a physician or a nurse, and they questioned whether sufficient attention is being given to the health needs of these families.

One-third of the families with children were given about 40 hours of the homemaker's time and one-third of the adult families about 8 hours during the week. Only a few households without children were given as much as 40 hours.

At present, Pennell and Smith reported, about 150 agencies provide

homemaker services, engaging about 1,800 trained homemakers. Of the families in the study, 52 percent received services through voluntary social service agencies; 30 percent from departments of public welfare, through child welfare or public assistance programs; and the remainder, 18 percent, from independent voluntary homemaker agencies, visiting nurse associations, or health agencies.

Nursing Service Influenced By Changes in TB Practices

Fundamental changes occurring in tuberculosis treatment and case-finding are challenging some traditional practices, stated M. Estelle Hunt, chief nurse, Tuberculosis Branch, Division of Special Health Services, Public Health Service.

In attempts to adapt practices to advancements made since the advent of chemotherapy, many new approaches are being tried, she said, and we are continuing to move toward great events in the field of tuberculosis.

Reviewing the situation in tuberculosis today, Hunt emphasized the "wide divergence of practices" in regard to hospitalizing patients, duration of hospitalization, bed rest, use of special tuberculosis hospitals, protective measures, and case-finding.

Recommendations for bed rest, for example, vary from several months to "when the patient feels tired," Hunt noted. Length of hospitalization varies similarly, from as long as 2 years to as short as 3 months.

There is general agreement on the desirability of patients having negative sputum before discharge, she said, but there is disagreement as to other criteria.

In case-finding, emphasis is being placed on selection of groups expected to show a high yield, selection of the initial test (chest X-ray or skin test), and limitation of testing to numbers for which adequate followup is possible. Tuberculin testing

is useful in selected instances, but at present it cannot be considered an alternate method of case-finding, Hunt observed.

The trend in hospitals is away from small isolated tuberculosis sanatoriums and toward the coordination of hospital services. In some States small sanatoriums are being closed, and one large tuberculosis hospital is being used for the entire State. In other States, the tuberculosis sanatoriums are taking patients with other pulmonary conditions and certain chronic diseases.

These changes and variations are bound to influence nursing, Hunt concluded. She believes, however, that they require adaptation of present services rather than initiation of new or different activities. She believes also that nurses must acquire an understanding of what is happening and nursing itself must identify the modifications needed.

Another consideration of utmost importance, she maintained, is the need for improved communication among all agencies and individuals concerned with the tuberculosis patient.

Communicable Diseases Invite Nursing Skills

Satisfactions derived from active participation in a program for protection against communicable disease are second to none of those provided in nursing, according to Mary R. Lester, chief, Nursing Section, Epidemiology Branch, Communicable Disease Center, Public Health Service.

Such a program, she explained, offers opportunities for individual initiative, teamwork, interagency cooperation, and community effort. It includes patient care, isolation and quarantine measures, prophylactic treatment, immunization, epidemiological investigations, improvement of environment, and individual and group education.

Her training in the requisite

by the age of 60. After analyzing the association between lipid level and risk of coronary heart disease, Dawber and his co-workers concluded that "the total serum cholesterol is associated with the development of coronary heart disease, the association varying according to age and sex."

In the examination of the geographic distribution of new coronary heart disease cases within the town of Framingham, 1 precinct was found to have a lower incidence than the other 7, and far lower than was expected (1 case out of 96 as opposed to 7.5 expected), but the investigators could find no explanation for the low incidence in this precinct.

A breakdown by nativity, the main groups being composed of native Americans of British and Irish ancestry and immigrant Italians, failed to indicate "any association between nativity and the risk of coronary heart disease," Dawber said.

Finds Mortality Rate Low Among St. Louis Jews

The mortality rate for Jews in St. Louis and St. Louis County, Mo., is nearly 14 percent lower than the comparable mortality rate for the total white population of the area.

Kurt Gorwitz, former director of the St. Louis Bureau of Vital Statistics, reported this finding following a study of all Jewish deaths (1,478) and stillbirths (25) which occurred during 1955-57, in comparison with the deaths in the total white population in the same period. The study used records of three firms found to handle virtually all funerals of persons of the Jewish faith in this area plus data on all other funerals where Jewish services were conducted.

Comparative data were shown for the total white population since Jews were found to represent less than 5 percent of this group and since age-adjusted mortality rates

for the nonwhite population were substantially higher.

In the United States, Jews are believed to have a lower birth rate and to be somewhat older on the average than the comparable white population. This makes the disparity in the mortality rates even more striking, Gorwitz remarked.

Accounting for some of this difference in rates was the fact that both the estimated Jewish infant death rate and the estimated Jewish stillbirth rate are substantially lower than the comparable rates in the total white population. The annual Jewish death rate, Gorwitz found, was between 10.3 and 12.6, while the Jewish stillbirth rate was between 7.5 and 9.2. Among the total white population, the annual infant death rate was 20.7 and the annual stillbirth rate was 14.5.

For most causes of death, Gorwitz observed, the rates were considerably less for Jews than for the total white population: for accidents, 60 percent; cirrhosis of the liver, 72 percent; tuberculosis, 80 percent; syphilis, 29 percent; and suicide, 13 percent. Jewish rates were slightly lower for heart disease, cancer, and vascular lesions. They were substantially higher for diabetes and hyperplasia of prostate. The difference in the two cancer mortality rates is entirely accounted for by a much lower Jewish rate for the genitourinary site group. No Jewish deaths were found from cancer of the cervix. This, Gorwitz believes, may be due to the Jewish practice of circumcising the male infant.

In accidents due to motor vehicles or falls, Gorwitz found the same disparity that existed for the total accident figures. He felt that the difference in motor vehicle death rates may be partially due to "the general absence of alcoholism in our Jewish population," while the difference in falls may be due to more adequate care received by elderly Jews. No Jewish deaths were reported from acute alcoholism.

The mean age at death for Jews was 66.7; for the total white population it was 64.4. Data were not

available, however, to compute age-specific death rates and life expectancy figures, Gorwitz said. He found that a larger percentage of Jews died between the ages of 45 and 84 than in the general white population while a smaller percentage died in all other age groups.

Two Out of Three People Have CVR Condition

Two-thirds of the people who died in Hartford County, Conn., in 1954 suffered from some kind of cardiovascular-renal (CVR) disease, according to Robert J. Keehn, biostatistician, and Dr. Henry Eisenberg, public health internist, Connecticut State Department of Health.

Out of a total of 5,162 death certificates for 1954, 2,810 gave CVR as the underlying cause of death, and 637 others mentioned CVR, Keehn and Eisenberg said.

In this study, by which the authors sought to describe the frequency of secondary CVR disease present at death and the prevalence of these diseases in the general population, some of their main findings were:

1. Beyond the age of 1 year, existing CVR conditions are as likely to be the underlying cause of death in one age group as in another. The proportion of secondary CVR conditions (deaths not caused by CVR diseases but mentioning them) was lowest in the age group 1-24, and highest at 75 years of age and older.

2. The proportion of underlying non-CVR deaths with mention of a CVR condition in a given age group is the same for males and females, while underlying CVR is relatively more frequent among males.

3. A higher proportion of underlying CVR deaths was observed in nonwhites than in whites for each age group beyond age 25.

4. The relative frequency with which CVR disease is given as the underlying cause of death is similar for native- and foreign-born white persons at all ages.

smokers as among persons who had never smoked," commented Dr. William J. Zukel, of the Office of the Surgeon General, Public Health Service.

This finding emerged from a study in six counties in northeastern North Dakota in 1956-57, in which private physicians, the North Dakota State Department of Health, the North Dakota State Heart Association, and the Public Health Service participated. Dr. Zukel's co-workers were Dr. Robert H. Lewis, Dr. Robert C. Painter, Dr. Lloyd S. Ralston, Dr. Robert M. Fawcett, Phillip E. Enterline, Alla P. Meredith, and Beatrice Peterson.

From the total population of 106,000 in six counties, a 10 percent probability sample consisting of 1,886 men 35 years of age and older was drawn and interviewed regarding their personal characteristics, habits, and occupation. During the following year, 228 cases of coronary heart disease developed from the total population of men 35 years of age and older; 160 of them had no previously diagnosed manifestations. They, or their survivors, were interviewed for the same factors, and in addition a detailed dietary interview was administered. This general interview and special dietary interview were also administered to an age-matched subsample of the 1,886 men initially identified, thereby providing controls representative of men in the general population.

Occupation seemed to be a factor in the different incidence rates obtained for smokers and nonsmokers. No appreciable difference was observed, Zukel said, between farmers who smoked and farmers who did not, but in other occupations the incidence rate of coronary heart disease was twice as high for smokers as for nonsmokers.

Moreover, Zukel pointed out, with regard to mild manifestations such as angina pectoris or coronary insufficiency, farmers and nonfarmers reported similar incidence rates. But the reported incidence of severe manifestations such as myocardial

infarction or death "was twice as high among other occupational groups as it was among farmers." And this difference was observed in every age group above 35 years.

Heavy physical labor was found to be inversely related to the incidence of coronary heart disease. "Men whose usual occupation required no heavy physical work," Zukel said, "have an incidence rate more than three times as high as those whose usual occupations required some heavy physical work." Unfortunately, he added, the information obtained by interview on physical activity appeared to be unreliable, and additional study will be necessary to obtain more precise information.

In comparing the detailed dietary histories for 162 of the 228 coronary cases reported and for 324 controls, Zukel and his associates found that regardless of how the cases were defined there were no significant differences between cases and controls in mean calorie intake, total fat consumption, or other major dietary constituents. This uniformity of dietary intake between coronary cases and controls, Zukel said, does not necessarily mean that dietary factors may not be important in the development of coronary heart disease, but it does demonstrate the probable importance of factors other than diet in determining why, in populations on relatively high-fat diets, some people have coronary heart disease and others do not.

Several Factors Related To Heart Disease

Education, smoking, and cholesterol levels were found to be related to the incidence of new heart disease cases in Framingham, Mass., in the sixth year of followup. No significant associations were discovered for nativity.

In the Framingham study, which will extend for 20 years, the National Heart Institute is investigating factors related to the development of cardiovascular disease. Dr.

Thomas R. Dawber, chief of the Institute's Epidemiology Section, worked with Dr. William B. Kannel, Dr. Nicholas Revotskie, Dr. Joseph Stokes III, Dr. Abraham Kagan, and Tavia Gordon in compiling and analyzing the sixth year data.

Nearly 5,000 adults, 29-62 years of age, who were free of coronary heart disease at the time the investigation began comprised the study group. The report was restricted to findings on men between the ages of 45-62.

As education increased, the incidence of coronary heart disease decreased, Dawber stated, adding that "even if allowance is made for the fact that younger men tend to have more education than older men, the trend remains unaffected." An excess incidence was confined to those who were graduated from but did not go beyond grade school, he said. These had a higher incidence, however, than those who did not finish grade school.

If all new coronary heart disease, excluding angina pectoris, is considered, Dawber pointed out, "an association of risk with cigarette smoking emerges, and this risk rises with the number of cigarettes smoked per day." However, he went on to say, "the mechanism by which smoking might be involved in the production of coronary heart disease remains obscure. There is no experimental evidence that smoking (nicotine) damages the blood vessels."

Dawber reported that in seeking some factor associated with smoking that might be important in the pathogenesis of the disease, a "most striking association" was discovered between the consumption of alcohol and the use of tobacco: as smoking increased, the amount of alcohol consumed increased, particularly in the lower age group. "Alcohol consumption per se, however, does not show any relation to the development of coronary heart disease," he said.

With regard to cholesterol levels and coronary heart disease, Dawber and his co-workers found the association strongest in young men; it seemed to disappear completely

throughout the stay in the hospital nursery.

The child will be given a psychological examination at 8 months and at 30 months to evaluate growth and development, a neurological examination at 12 months to screen for defects of the nervous system, a general pediatric examination at 42 months, and a final evaluation at 72 months which will include detailed studies of general physical and neurological status. In addition, interval histories of the child will be obtained every 6 months, Masland stated.

Since the 40,000 pregnancies may not result in a sufficient number of damaged children to yield significant conclusions, data on a larger number of such children are necessary. Information will be sought on other patients of the collaborating institutions and patients of other institutions and agencies in the localities of the research centers for this extensive phase of the project.

Masland asked for comments and suggestions on the methodology and organization of this phase, which is still being developed. Its success will depend to a considerable extent on the selection of key items of information required and on achieving methods of obtaining data from this extensive phase which are identical to, or at least comparable with, the same items derived from the intensive phase of the study, Masland declared.

Advocates New Concept, Prenatal Human Ecology

The concept of prenatal human ecology rather than pregnancy wastage should govern investigations of the influences upon acquired congenital anomalies, maintained Dr. Theodore H. Ingalls, professor of preventive medicine and epidemiology, University of Pennsylvania School of Medicine.

He feels the term pregnancy wastage is "scientifically a vast understatement" and that the main pat-

ternus of causation emerging make it clear that the study of congenital anomalies embraces a great body of human ecology, not merely the products of pregnancy.

We are but on the threshold of the knowledge we need to protect the health at birth of future citizens, he said. Today's proof that controllable maternal illness may distort fetal development stems mostly from clinical observations made in the 1940's of the impact of rubella on the conceptus when the infection is acquired by the mother during the first trimester of pregnancy, he stated.

Ingalls called casefinding the bottleneck in acquiring the necessary knowledge. Not only are clinical manifestations of deforming disease in the embryo hidden, but the final pathological consequences seem relatively nonspecific. Congenital cataract, deafness, heart disease, and dental defects are not pathognomonic of rubella; they may be observed in babies with no maternal history of antecedent illness.

Also direct biologic relations between mother and conceptus are involved in the interrelations which have virological, immunological, embryological, physiological, and purely obstetrical facets.

As an example, he cited Asian influenza, a disease whose teratogenic hazard is unknown. Not only does it present casefinding difficulties similar to rubella, but maternal infection has no visible pathognomonic signs.

In Pennsylvania, where the occurrence of selected kinds of anomalies have been recorded on birth certificates for a decade, there is no evidence of a cause and effect relationship between Asian influenza in the fall of 1957 and congenital anomalies reported in the babies born 7-8 months later.

But influenza cannot be acquitted on the strength of such data. Birth certificates do not show the true extent of congenital heart disease at birth, nor are all cases of mongolism, cataract, and the like discovered in the first days of life.

Furthermore, all anomalies cannot be lumped together in order to test reasonable hypotheses. So many variable causes produce so many variable effects that some isolation of both anomalies and factors to be studied is necessary. For example, it is quite possible that maternal infection with Asian influenza may result in congenital deafness, as rubella did in Australia, but not influence measurably the occurrence of cleft palate. We just do not have the requisite data to test such speculations, Ingalls said.

Congenital defects involve much more than infectious agents. Recent studies indicate that testosterone injections of the mother during early pregnancy may induce anomalies of the perineal and genitourinary structures. And antithyroid drug therapy and carbon monoxide poisoning may be teratogenic agents. A woman experiencing diabetes while the fetal islets of Langerhans are differentiating may be suspect of initiating a disturbance of sugar metabolism in her unborn baby that may show up in the future.

Other significant metabolic, gynecological, systemic, anesthetic, traumatic, and X-ray-induced disorders of pregnant women are at least suspect of carrying a risk for the conceptus. The list of agents, combinations of agents, and degrees of activity is long and the list of possible consequences is longer still, Ingalls stated.

The appraisal is a challenge to medicine as much as to preventive medicine and public health. Every mother is an incubator for her own baby; gynecological and obstetrical techniques and knowledge should be applied to evaluate thoroughly pregnancies which result in the birth of deformed children, he declared.

Planned Parenthood Service In North Carolina

Over the past 21 years, a planned parenthood service has demonstrated its value as an effective part

5. No difference was observed in the relative frequency of CVR deaths or secondary conditions of CVR when classified by population sizes.

6. Among deaths resulting from non-CVR diseases, but with CVR conditions frequently mentioned on the death certificate, were rheumatic fever, diabetes, hyperplasia of the prostate, appendicitis, ulcer of stomach and duodenum, and pneumonia. Rheumatic fever had the highest frequency of mention (100 percent) and pneumonia lowest (50.6 percent) of this group of diseases. Together, they accounted for 24.5 percent of the mentioned CVR diseases.

7. Diseases of the arteries and nephritis and nephrosis formed a higher proportion of secondary CVR conditions than of underlying causes of death.

8. The prevalence of CVR diseases in the general population of Hartford County was estimated to lie between 10 and 23 cases per 100 persons.

Keehn and Elsenberg believe that with a knowledge of these prevalence rates, heart disease control measures can be established "on a sounder program, personnel, and financial basis."

Uses Family Members As Epidemiology Controls

Use of family members as controls to ascertain the etiology of disease was discussed by Dr. Arthur S. Kraus, chief of the division of vital records and statistics, Maryland State Department of Health.

Kraus employs a sample of new cases of disease with a control group consisting of family members, during a specified period. A member is eligible for the control group if he is free of the disease at the beginning of the period.

After pairing afflicted persons with their proper controls, Kraus tabulates the pairs according to a physical or environmental factor that is antecedent to the occurrence

of a disease and is presumed to be pertinent. A relative incidence rate is then estimated using the ratio of pairs in which the case has the antecedent factor and the control does not and pairs in which the case does not have the antecedent factor and the control does.

After presenting the theoretical constructs in such analysis, Kraus applied the method to the cases of heart disease which subsequently occurred in the Donora, Pa., population exposed to the 1948 smog. His findings confirmed and strengthened the previously noted association between acute illness during the smog and subsequently reported heart disease. Kraus speculated that the smog served primarily as a diagnostic screening test rather than as an etiological agent for subsequently diagnosed heart disease.

Kraus concluded that there are certain circumstances in which it is impossible or inadvisable to use the family control method. The method

should be eschewed, he advised, when (a) the antecedent factors are indeterminable after the disease has been diagnosed, (b) there are too few pairs of cases and controls in which the two differ with respect to the antecedent factor under study, and (c) the disease occurs predominantly or only in one sex under those conditions in which sex is associated with the antecedent factor, and spouses are the only available family member.

The advantages of the family method, when it can be applied, Kraus said, are (a) relative incidence rates can be estimated from comparatively small samples, (b) certain sources of positive relationships due to nonetiological factors can be eliminated, and (c) it is comparatively easy to find new cases of a disease and controls among family members to yield an estimate of a relative incidence rate that can be generalized to other families.

Maternal and Child Health . . .

Fifteen Centers to Study Reproductive Failure

Fifteen research centers will join in an intensive epidemiological study of reproductive failure, encompassing 40,000 mothers and their children from pregnancy up to age 6 years.

Dr. Richard L. Masland, assistant director, National Institute of Neurological Diseases and Blindness, Public Health Service, described the collaborative project, which is supported by Federal grants.

Its objective is to develop a series of examinations which will permit an evaluation of the independent operable variables during pregnancy and also permit detailed, accurate differentiation of the types of abnormalities observed. Extensive, detailed information will be col-

lected from the pregnant women, and their offspring will be observed and evaluated until they can be definitively categorized.

The evaluations in this prospective study will be based upon an extensive schedule of examinations, Masland explained. During the prenatal period data on the socioeconomic status, family history, and past medical history of both parents will be obtained, and gynecological and physical examinations and special serologic tests for virus infections during pregnancy will be conducted.

The process of labor and delivery will be observed, and pathological examinations made of the placenta and of any children dying at birth or during the course of the study. The neonate will be examined in the delivery room and periodically

and inconsistent in disciplining the children. In all these cases, if the opportunity had been available, the underlying pathology and poor adjustment might have been identified before the child entered school, Oppenheimer and Mandel observed.

They felt that their findings corroborated the belief, widely held in the professions engaged in helping children in trouble, that emotional disturbances do not occur suddenly. If the difficulties of adjustment of school children are to be considered intelligently, emotional disturbances and their background of tensions in parent-child relations must be recognized and treated in the preschool period, Oppenheimer and Mandel concluded.

Otitis Media Prophylaxis Used for Indian Children

Regular doses of sulfamethoxypropyridazine were an effective prophylaxis for otitis media in a study of 120 Indian children reported by Dr. Paul R. Ensign and Mabel Moran, of the *City-County Health Department*, and Dr. E. M. Urbanich, County Welfare Medical Center, Great Falls, Mont. A prophylaxis was sought because a large number of Indian children in the Great Falls area had draining ears and earaches.

For the study the dose rate, varied according to the child's weight, was $\frac{1}{4}$ to $1\frac{1}{2}$ tablets or $\frac{1}{2}$ to $2\frac{1}{2}$ teaspoons of syrup each Monday, Wednesday, and Friday for approximately 6 months during the winter of 1957. Maximum age of the children was 11 years. The control group was composed of 130 children of similar ages on the welfare medical rolls of the county. Otitis media is defined as an infection of the middle ear resulting in draining ears or an earache of one night's duration.

Of those taking the medication regularly, 34, or the entire group, with no history of draining ears and 15 of 18 with such histories did not

develop otitis media. Eighteen children took the medication irregularly; none had draining ears during the winter.

Nineteen children had otitis media during the period of the study. Of these, 12 stopped taking the drug at least 2 weeks prior to the onset of the condition, 3 took the medication regularly but already had mutilated or destroyed eardrums, 2 took the drug irregularly, and 2 did not take it at all.

The authors found that the drug successfully prevented otitis media in children with draining ears, provided the eardrums had healed, but was less successful with children whose eardrums were destroyed or badly mutilated.

Although 23 percent of the study group had histories of draining ears compared with 14.6 percent in the control group, in the period of the study only 6.6 percent of them had draining ears, compared with 15 percent of the control group, the authors stated.

Family Health Clinic Unifies Obstetrics and Pediatrics

A clinic, reaching entire families with unified obstetric and pediatric services and using the skills of many disciplines, not only gave high quality care but also provided a vigorous resource for staff development, stated Dr. Pauline G. Stitt, assistant professor of maternal and child health, and Dr. Joan Babbott and Dr. Eva J. Salber, Milton Research Associates in Maternal and Child Health, Harvard School of Public Health.

The special family health clinic, a pilot project at Boston Lying-In Hospital, attempted to minimize artificial separations in the health services provided for families during childbearing and rearing.

The care provided by the clinic was based upon these premises: that pregnancy, childbearing, and child rearing are a continuum; that these processes intensify difficulties

and add new ones to daily existence; that the way in which these difficulties are met has an immediate and long-range effect; and that the services of the clinic should enable the family to master the crises of pregnancy and child rearing and derive strength from these experiences.

The clinic was open to mothers, fathers, and children and offered family-focused service. Obstetric, pediatric, nursing, nutrition, and social work services were provided to 116 families having their first babies and 25 of these families during subsequent pregnancies. A psychiatrist acted as mental health consultant for the project.

Obstetric, and pediatric services were provided with considerable flexibility. Pediatricians participated in early prenatal care; pediatric visits began a month after the baby's birth and continued throughout the first year. Families saw 3 or 4 staff members per visit, and, as far as possible, were cared for by the same personnel throughout their clinic experience, the authors said.

All observations on a family were assembled in a single unit record. The staff also pooled information on families in preclinic and post-clinic case conferences of the entire staff, in conferences between staff members and with the mental health consultant, and in administrative staff meetings.

The sharing of prenatal observations revealed from 6 to 40 pertinent clues per family, case analyses showed. Pediatricians were already well acquainted with the family when they started work with a newborn infant and thus could give custom-fitted counsel rather than general observations in dealing with behavioral situations and emotional disturbances. Warned by colleagues of impending family predicaments or present difficulties, they avoided unwittingly contributing to such situations.

The staff benefited from the association with persons of other disciplines. For example, pediatricians, collaborating with nutritionists, devised feeding practices geared

of the maternity care provided in public health clinics in North Carolina, stated Dr. J. W. R. Norton, director, Dr. J. F. Donnelly, obstetric consultant, and Anne Lamb, nursing consultant, North Carolina State Board of Health.

Although the maternal, prenatal, and late infant mortality rates for the State began to decline before 1937 when planned parenthood was added to maternity care in the clinics, the service has been a factor in the decline, according to the authors (see chart).

They described some characteristics of the service available in clinics in 74 of 100 counties in the State. The service is directed toward the production of healthier offspring who have a greater chance for survival and a greater opportunity of reaching their full potentialities by the spacing or the prevention of pregnancies because of medical indications or socioeconomic considerations, usually both.

Since its inception, the planned parenthood service has won acceptance quietly, without fanfare.

After the service has been explained to and approved by local health departments and county medical societies, county boards of health accept or reject it as a part of their maternal and child care.

Methods of providing the service vary. The patient may be referred to the staff of a hospital or outpatient department or to a private physician, or the health department clinic may provide the service under the supervision of its director or a private physician. Generally physicians and nurses have provided such services in a balanced maternal and child health program.

In recent years, 12 to 14 percent of the total number of women delivered in North Carolina have received prenatal care in public health clinics. In 1957 obstetrical patients averaged 3 prenatal visits per pregnancy, more than 40 percent returned for at least one postpartum visit, and nearly 20 percent were patients who had received instructions and facilities for spacing pregnancies.

The present practice is to discuss

family planning during the prenatal visits so that by the time of the postpartum examination the patient has had time to think about it and reach a decision, the authors explained.

The planned parenthood services of the public health clinics in North Carolina are as much a part of the maternal and child health care as physical examinations and laboratory tests, the authors declared.

Twigs Bent at Home Before School Begins

To prevent school children from developing behavioral disturbances, Dr. Ella Oppenheimer, chief, and Margaret R. Mandel, consultant in psychiatric social work, bureau of maternal and child health, District of Columbia Department of Public Health, advocated adding social casework and psychological and psychiatric counseling to the basic pediatric and public health nursing services of child health clinics.

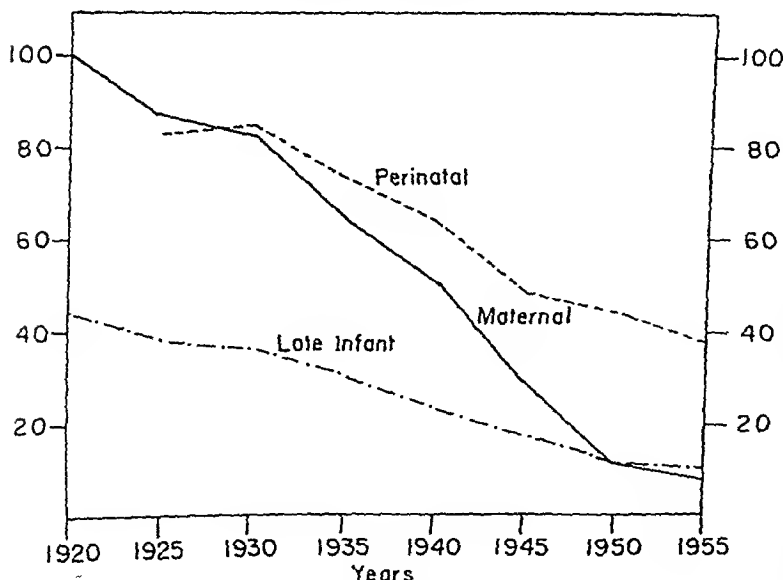

In a study of 60 school children, 32 showed evidence of emotional disturbance in the preschool period, 20 in kindergarten, 5 in the first grade, and 3 in the second grade.

Because of their disturbed behavior the children had been referred to the psychiatric, diagnostic, and counseling clinic of the school health services. The clinic, a limited pilot project staffed by a part-time psychiatrist and a full-time social worker, served school children with emotional problems.

The children ranged in age from 5 to 17 years; 41 were boys and 19, girls. Factors of organic origin, which could have been detected in the preschool period, contributed to the disturbed behavior of 14.

Among 18 illustrative case histories cited, 15 children had disturbed relationships with parents, siblings, peers, and teachers. In 9 cases parents had severe marital problems, in 9 the father was absent from the home most of the time or was a weak masculine figure in the family, and in 8, mothers were weak

Maternal, perinatal, and late infant mortality rates in North Carolina, 1920-55.

NOTE: Maternal mortality rates per 10,000 live births; perinatal and late infant mortality rates per 1,000 live births.

pediatric care of orthopedically handicapped children; and more continuity of care by the same physician seeing the child on each visit. The authors also found that the professional nursing time assigned to outpatient services could be used more productively in counseling patients than in carrying on routine activities.

The small number of clinics (6 out of 20) making referrals to public health and visiting nurse services indicated the need to strengthen this aspect of home followup. Although all the hospitals had good social service coverage on the inpatient service, only one-fourth had social service workers present or easily available during clinic sessions. Not only strengthened social services but also a closer liaison between the doctors, nurses, and social workers in making a medical social plan for patients were indicated.

There were no followup methods in 12 clinics and only poorly functioning ones in 2. An efficient plan for followup is applicable to all types of service and is essential to a well-functioning clinic, the authors stated.

Suggest Changes

Adults and children were seen together in the same clinic in 10 hospitals. The authors suggested that if a separate clinic is not feasible, a portion of the regular clinic should be set aside for children.

This grouping would enable the pediatric staff to observe children with orthopedic handicaps more closely resembling those seen in a private pediatric office than those seen in the inpatient service.

The upper age limit for children varied from 12 to 17 years. The authors proposed that children's clinics accept patients up to 17 years, the age of termination of growth and osseous maturity.

All clinics visited had an appointment system but only two had time appointment systems. Specific time appointment systems had been found unsuccessful but divided sessions

were very efficient. Sessions divided into early, middle, or late periods were recommended. In 13 of the 20 clinics, extra visits were necessary for X-rays. Only one hospital had a separate, adequate waiting room with good recreational facilities for children.

Based on the observations made during the survey of these 20 services, standards for orthopedic outpatient services are being developed by the New York City Health Department.

Pediatric Evaluations Of Indian Children

Pediatric evaluations of 214 Indian children of the Wind River Reservation in Wyoming indicated that their needs were similar to those of non-Indians of similar socioeconomic status, declared Dr. Georgia B. Perkins, medical director, and Gertrude M. Church, nursing consultant, Denver Regional Office, Children's Bureau, Department of Health, Education, and Welfare.

The pediatric evaluations included medical histories and social and emotional aspects of the child and his family as well as chest X-rays, detailed blood examinations, serologic tests for syphilis, rectal tapes, stool examinations, and a height and weight check of the children.

The evaluations, the authors declared, were more valuable to these families than multiple screening, because of the greater health education values that resulted and their greater validity in future health planning.

The families' cooperation and acceptance of the evaluations the authors attributed to previous visits by the public health nurse to explain the examinations and the followup. A review of medical, nursing, and social service records of the families prior to the evaluations was valuable, productive, and a good case-finding method, Perkins and Church noted.

The children, each accompanied

by an adult, were members of 60 families; 50 percent were Shoshones, 48 percent Arapahoes, and 1.4 percent were of other tribes. They ranged in age from less than 1 to 12 years.

Followup Needed

The evaluations, performed by 7 non-Indian pediatricians, revealed that 201 children required some kind of followup. Dental care was indicated for 135, although such care was available to them at the clinic on the reservation. The low level of immunizations completed—99 children lacked DTP immunization, 135 smallpox, 142 poliomyelitis, and 107 Rocky Mountain spotted fever—suggested that well child supervision was needed.

Medical care of some kind was indicated for 137 children. Of these, 64 had ear and hearing difficulties, including 37 with otitis media; 23 had visual defects including myopia and strabismus; 19, orthopedic abnormalities; 9, congenital abnormalities; 16, infections other than otitis media or intestinal parasites; 16, metabolic, nutritional, or endocrine disorders; 5, convulsive disorders; 3, indications of possible tuberculosis; 4, indications of possible cardiac abnormalities; and 1, mediastinal mass.

The 212 rectal tapes and 70 stool specimens examined showed that 21.2 percent of the children had pinworm ova, and 20 percent had pathogenic intestinal parasites.

Generally the children were somewhat shorter, particularly the Shoshones who were considerably shorter and also lighter, than their non-Indian counterparts. Because of this difference, individual growth histories will be necessary until tribal data on height and weight are available, the authors stated.

Assistance with social problems is one of the greatest needs of the Indians, according to Perkins and Church. Although only six children were identified as having emotional difficulties in the pediatricians' interviews with parents, the authors felt that possibly more intensive

to a child's motor, social, and adaptive development. Pediatricians and nurses jointly reexamined their pediatric and nursing practices in terms of their experience in the clinic. The data, selective perceptions, and interpretations of the social workers helped other staff members comprehend more completely the child's place in the family milieu.

The psychiatrist supplied a mental health perspective of family life. While alert to signs of incipient trouble, he contributed chiefly by making others aware of signs of family strengths and in showing the staff how to use those strengths to build a healthy family life.

The multidiscipline approach also helped to efface stereotypes the members of one profession had of another and led to improved communication, the authors stated.

They suggested that such a clinic may be valuable in raising standards of care in maternal and child health programs. In addition to their services in the clinic, participants carry over into other functions the insights gained during the experience. Methods, to a varying degree, can also be applied elsewhere.

Sound Planning Basic In MCH Services

Three considerations in the orderly development of maternal and child health care were listed by Dr. Edward R. Schlesinger, associate director, division of medical services, New York State Department of Health.

These are services which utilize personnel and funds efficiently; gradual increase in the depth of those services; and restriction of frank experiments or demonstrations to projects that are likely to become regular services. He cited as an extreme example of unsound planning, setting up a modern premature infant care center in a locality where mortality rates are

high among infants over 1 month of age. Services to insure safe milk and water supplies and instruction in proper infant care should come first, he said.

However, in these circumstances a modern premature center can focus attention on modern pediatrics in contrast to the conditions which led to the death of many full-term infants, Schlesinger added.

He contrasted the experimental demonstration, which tests new techniques or reevaluates existing ones and has a definite goal, with the service demonstration, which has a less definite objective or endpoint. A voluntary agency may demonstrate disease prevention or detection to gain support, but community acceptance may encourage the agency to continue the demonstration instead of switching its efforts to other health needs, Schlesinger said.

He described how a cooperative effort in New York State hastened the shifting of secondary prevention of rheumatic fever from voluntary to official auspices. For years, local chapters of the State Heart Assembly subsidized the prevention of recurrent attacks in rheumatic children. Only a few local health departments accepted State aid, made available a few years ago, to pay for drugs and services.

At a 1957 conference, State and local government agencies agreed that rheumatic fever prophylaxis should be an official responsibility. Since then, there has been a rapid shift toward health department support of secondary prevention.

Extending comprehensive demonstration programs in limited areas to an entire State is somewhat more difficult, according to Schlesinger. Ten years ago, a demonstration in premature infant care was started in two regions of upstate New York. Payment for care was envisioned as a means of improving care for premature infants throughout the area.

As the demonstration phase was concluded several years ago, premature infants were considered physically handicapped children under State law, and counties wanting pre-

mature infant care programs could obtain State aid. Although high standards in facilities and personnel were required for approval, all but one of the counties in the demonstration area elected to continue under State aid, and several additional hospitals were approved as premature centers.

Initially, spread of the program outside the demonstration area was slow because of the need to build community interest and the time required to renovate or construct premature nurseries and train pediatricians and nurses. But the program is gradually influencing a larger area of the State, Schlesinger said.

He concluded that selling communities on programs showing the greatest promise of results is more productive than developing services unrealistically to meet so-called "felt needs."

Child Orthopedic Clinics Surveyed in New York

Improved and broadened services to encompass early casefinding, medical and paramedical care, and efficient followup in 20 children's orthopedic clinics in New York City were recommended by Dr. Robert S. Siffert, senior orthopedic consultant, Margaret A. Losty, acting director, and Sylvia B. Snyder, senior social work consultant, of the bureau for handicapped children, New York City Department of Health.

In 1957 the authors, prompted by the steady decline in the inpatient census and the concomitant increase in the number of children being treated on an outpatient basis, surveyed 20 outpatient departments of the orthopedic services participating in New York City's crippled children's program.

The survey revealed the following needs: more closely integrated inpatient and outpatient care; strengthened medical service through increased attending and resident staffs in outpatient services; strengthened

He felt that the President's Council on Youth Fitness had been wise to resist demands for federalized testing standards and their routine, periodic application to all young people. Fitness, he maintained, belongs in the hands of the educators and physicians working at the local level who are deeply concerned with the health, welfare, and fitness of young people.

What is the measure of fitness, if it cannot be measured by any set of physical tests? he questioned. First we must ask, for what purpose do we desire fitness? Each person has

individual aims. He may seek success in a profession, a business, a sport, or an art. These are but superficial goals, which although desirable, are far from all of life, Bauer declared.

To be loved by our relatives because we are lovable, to be esteemed by our fellow workers because we are estimable, to be valued by our contemporaries because of our worth, and to be mourned when we are gone because our absence is a real loss; these are the real objectives in living and the real measures of fitness, Bauer concluded.

This finding was reported by Dr. A. L. Russell, National Institute of Dental Research, Public Health Service, and Dr. Polly Ayers, director, bureau of dental health, Jefferson County Department of Health, Birmingham, Ala., following a non-random socioeconomic study of 2,150 dentulous white and nonwhite persons, 15-74 years of age, in Birmingham.

In the periodontal examination of these people, each tooth was scored for dental caries and periodontal disease. In the latter instance, each tooth was graded on a scale based on the classical clinical signs of marginal periodontitis (inflammation, pocket formation, and loss of function). Among their other findings were:

- Periodontal scores become progressively lower as education increases.

- Periodontal condition is directly related to the degree of neglect (unfilled dental caries, for example) in both classes at all ages over 20. Disease was more severe as the degree of neglect increased.

- Scores were lower in those who enjoyed occupations high in prestige and income. For both white and nonwhite persons, the data suggest that education is more closely associated with periodontal condition than occupation is.

- There were no differences in the periodontal condition of white and nonwhite groups of equivalent socioeconomic status.

Russell and Ayers recommended that comparisons between white and nonwhite populations should be based on groups of equivalent socioeconomic status.

Dental Care . . .

Dental Neglect Varies With Social Class

The role of social class in forming attitudes toward dental care was accentuated in a pilot motivational study sponsored by the American Dental Association and carried out by a specialized Chicago firm. B. Duane Moen, director of the association's bureau of economic research, described the study as a pioneer effort.

Since direct questions do not usually give valid clues to behavior, said Moen, the sample of 126 men, women, and children representative of a typical midwestern community were stimulated to talk freely by such queries as, "What have been your experiences with dentists?" Sentence completion and picture interpretation tests were other devices.

Moen gave these results, grouped according to accepted classifications of social status:

- The upper middle class, professionals and business executives, with characteristic foresight, values dental services to prevent tooth decay or to defer it if unavoidable.

- The owners of small businesses, minor executives, teachers, salesmen, and white collar workers com-

prising the lower middle class take the typically moralistic view that dental care is a duty. Attractive teeth are important as a social asset.

- Those in the upper lower class, skilled and semiskilled blue collar workers, with a recent income rise, appreciate dental care far more than those in the next lower category. The best opportunities for behavioral and attitudinal changes are here.

- Members of the lower lower class show the most dental neglect, but not because of lack of information. Tending to live for immediate gratification, they consider dental care too much trouble.

Although dental health education is effective, the study pointed out that ways are needed to motivate people to related action. There is little reward associated with dental care, but much punishment from neglect. "Motivational efforts are mainly negative," it was concluded.

Oral Debris Indicted In Dental Study

Persons with obvious oral debris have substantially more periodontal disease than persons with relatively clean mouths.

Untreated Cleft Palates Compare with Treated

Tentative conclusions on the biosocial effects of unoperated oral clefts were reported by Dr. Frank E. Law, Division of Dental Public Health, Public Health Service, and Dr. John T. Fulton, professor of

medical social work would reveal additional social difficulties.

Findings in family medical histories of significance to the children included 3 women who were possibly prediabetic, 1 family with both parents diagnosed as diabetic, 2 families with histories of rheumatic fever, 2 with an unusual number of deaths among siblings of the child examined, and 4 with untreated tuberculosis in the household.

The pediatrician, estimating the reliability of the data they secured, felt they had obtained fair or good pediatric histories on 78 percent of the children and poor histories on 21 percent.

The authors concluded that by offers of similar evaluations and followup services to other groups, adult Indians may be persuaded to cooperate in assessing health status and in public health endeavors.

Multiple Antigen Booster Proves Effective

A booster dose of a multiple antigen has proved to be extraordinarily effective in increasing poliovirus immunity to high levels, declared Dr. C. Dale Barrett, Jr., director of maternal, child, and school health, Detroit Department of Health, and Dr. Eugene A. Timm, research virologist, Parke, Davis and Company, Detroit.

A series of inoculations of the antigen, containing diphtheria and tetanus toxoids and pertussis and poliomyelitis vaccines combined and adsorbed on aluminum phosphate, were administered to 224 children drawn from the child health clinics of the Detroit Department of Health.

Beginning in July and August 1956, children 6 months through 5 years of age received 3 monthly injections of 0.5 ml. per dose, and infants under 6 months received 4 similar injections. Booster injections of the multiple antigen were given 15-18 months later to 52 of the 224 children. At this time a control group of 51 children of corre-

sponding age range who, by history, had never been immunized with poliomyelitis vaccine, were admitted to the study and received a single 0.5-ml. dose of the tetravalent vaccine.

Antibody levels were determined from blood specimens taken prior to each injection and 2 weeks after the final injection in the primary series and the booster dose.

Prior to the first injection, 76 children had no demonstrable antibody to any type of poliovirus. Of these, 98 percent showed significant antibody response to type 2 poliovirus, 89 percent to type 1, and 69 percent to type 3 following the primary series.

Barrett and Timm found that the booster dose greatly enhanced the seroimmunological response to the poliovirus antibody and the response to the other components of the antigen. After the booster injection, more than 97 percent of the 52 children had high antibody levels to all three types of poliovirus.

According to the authors, this demonstrates that essentially all of the children benefited from the primary immunization, and that the antibody level demonstrable after the primary immunization cannot be the sole criterion for evaluating antigenic potency.

The relatively poor response in the control group of 51 children to the single dose of multiple antigen substantiates the conclusion that the marked response of those receiving the booster injections is truly a reinforcement effect, dependent on the primary series of inoculations, the authors stated.

Infants as young as 2 months of age responded to the primary injections with demonstrable antibodies to all antigenic components and reacted as well as the older children to the booster dose. After the fourth dose in the primary series, 80 percent of the infants exhibited significant levels of antibody with a marked improvement in the levels for each poliovirus type, compared with lower responses after the third dose.

No clinical reactions of any serious consequence were reported or observed, the authors stated.

Physical Fitness Held Not Sole Objective

Current emphasis on physical fitness is in danger of overshadowing the mental, moral, spiritual, and social fitness of the individual, stated Dr. W. W. Bauer, director of the bureau of health education, American Medical Association.

In accepting the William A. Howe Award of the American School Health Association, Bauer outlined a broad concept of fitness and suggested that mental, moral, spiritual, and social fitness deserve equal, if not stronger emphasis than physical fitness.

He noted a confusion between the concepts of health and fitness. "Can one be fit and not healthy?" he asked, and declared that he did not believe health alone constitutes fitness. Health can be passive, languid, mere freedom from disease. However fitness is inherently dynamic; it is hard to imagine a passively fit individual, he stated.

There is no question that health contributes to fitness, but can there be fitness in the absence of health? he asked.

He cited the celebrated epileptics Lord Byron and Julius Caesar, Chopin and Robert Louis Stevenson with tuberculosis, the alcoholic Stephen Foster, Lincoln with his black moods of depression, and Lord Nelson with but one arm and one eye as persons who surmounted disease and defects.

There have been demands for a series of exercise and achievement tests to measure the fitness of an individual, he said. Tests could be devised to measure physical performance. "It would, however, be the height of fallacy to assume that such a measurement of physical strength, endurance, and agility is any criterion of the total personality fitness of an individual to meet the challenge of living," Bauer stated.

provide for themselves, Aaron posed these questions:

- What constitutes minimum dental care essential for everyone and therefore for recipients of assistance?

- Is the program which is solely for emergencies pennywise and pound foolish?

- Do we know what added burdens inadequate dental care places on dependent children and on the disabled and the aged?

- Shouldn't the professions explore the effects of inadequate dental care on nutrition, speech, performance, and development of the individual's fullest potential?

- Do we need attitude studies of recipients, dentists, and the public to determine where we are and where we want to go?

Cinefluorography Facilitates Cleft Palate Therapy

Using cinefluorography with image intensification together with the sound spectroscope has proved invaluable in establishing presentable speech patterns for postoperative cleft palate patients, declared Dr. H. K. Cooper of the Lancaster Cleft Palate Clinic, Lancaster, Pa.

Interest at the clinic, he said, is focused on postoperative function of the structures involved because good physiological results do not always accompany a good anatomic closure of cleft palate.

The cinefluoroscope produces a moving picture which enables the therapist to study the physiological action of the pharyngeal muscles, soft palate, tongue, and lips. The sounds are reproduced simultaneously. The sound spectroscope converts the sounds of speech into a graph.

With this combination of devices, Cooper pointed out, the therapist is in a better position to diagnose the difficulties and offer a treatment plan for postoperative patients whose speech is faulty.

Study of the soft palate in nor-

mal function by "visible speech" proved that the greatest pharyngeal closure is always above the external tubercle of the atlas bone. Contrary to the theory that Passavant's pad is the point of greatest constriction of the superior constrictor muscle and that its forward movement is present in normal speech, cinefluorography showed evidence of this movement only in some instances where the palate is short.

Cinefluorography has been a decisive factor when redivision of the

soft palate was considered. It has also helped to decide whether to operate further or to advise construction of a speech appliance for a postoperative patient. Placing the appliance with a speech bulb always above rather than opposite the point of greatest constriction, the location of which is no longer a matter of conjecture, results in a better voice quality as well as a better velopharyngeal seal without disturbing retention of the appliance, Cooper stated.

Food and Nutrition . . .

Taste, Odor, and Cost Balk Food Irradiation

Russia is the first country to permit the sale of an irradiated food, stated Dr. L. E. Clifcorn, manager, central division research department, National Can Corporation, Barrington, Ill.

At the Geneva Conference on Peaceful Uses of Atomic Energy in September 1958, the Russians reported that on the basis of tests conducted the U.S.S.R. chief of public health inspection had authorized the use as food of potatoes irradiated with a 100,000 rad dose to prevent spoiling. The British reported that the destruction of *Salmonella* in frozen eggs appeared to be their most promising and compelling use for food irradiation.

Before American food processing companies can offer irradiated foods to the consumer, research must disclose what foods may be benefited by radiation and whether the benefits are sufficient to carry in the early stages the higher capital and operating costs and the costs of educating the consumer to accept foods having new sensory characteristics and possibly new cooking requirements, Clifcorn said.

He also pointed out that Food and Drug Administration approval must

be obtained before any irradiated food can be offered for civilian use.

Flavor and odor are the main problems, he said. The degree of off-flavor development is directly proportional to the radiation dose and can be controlled in some foods by irradiation in the frozen state, use of inert gas, or other techniques. For pasteurization treatment (200,000 rad or less) off-flavor is insignificant or less severe than for sterilization dosages, up to 4.5 megarad, required to destroy *Clostridium botulinum*. No residual radiation has been found in food even after it has been treated with 25 mev electrons.

Assuming food is to be irradiated at 2 megarad with a 50 percent energy utilization factor, a 10-kw. machine costing from \$100,000 to \$400,000 can treat 1,970 pounds of food per hour, Clifcorn said. The 10-year depreciation operating and maintenance costs are estimated at 2 cents per pound on an 8-hour single-shift basis. For sterilization at 4 megarad the cost is doubled. For low dosage treatment at 100,000 rad the cost drops to approximately one-tenth of a cent per pound, which is approximately the cost of steam-sterilization of the product of a single-line pea cannery. Low radiation doses are commercially the most attractive. Only expensive food

dental epidemiology, University of North Carolina.

Data on 124 native Puerto Ricans age 15 to 57 years were collected at 5 health centers. Of the 59 untreated subjects, 51 had cleft palates and 8 had clefts involving only the lip and alveolar process; 29 who had had surgical repair were included for comparison of treated and untreated cases, and 36 who had normal palates were included as controls for normal growth and speech of Puerto Ricans.

Law and Fulton said that the patients with unoperated cleft palates appeared to have developed well and their facial growth patterns were normal. Clinically the growth of the upper part of the face and of the dental arch was closer to normal in the unoperated than in those who had had early surgical treatment of the palate.

Better movement of the posterior pharyngeal wall during vowel phonation was indicated in the unoperated persons. These patients reported no more respiratory illnesses than the control groups, and although the turbinates were consistently abnormally enlarged, the eustachian tubes were usually patent and apparently functioning normally.

Individuals in the group had adapted rather well to speech difficulties, Law and Fulton declared. Patients with all types of clefts consistently omitted "k" and "g" sounds. Those with unrepaired complete clefts from the lip through the soft palate had near normal voice quality while those with a cleft of the soft palate only were most nasal. Speech of patients with untreated clefts involving the hard and soft palates seemed superior to the speech of patients with surgical closure of this type of cleft.

Study patients required more special assistance with hearing problems than normal individuals but less than surgically treated cases. Although social and emotional problems continue to plague these people, they reported that as children at home they were favored over their

siblings and were protected by their teachers at school. The majority had had considerable difficulty at school, Law and Fulton concluded.

Asian Dental Differences Explained by Fluoride

The differences in decayed, missing, or filled (DMF) rates in three Southeast Asian groups apparently can be explained by the differences in fluoride concentrations in the enamel of their teeth. This epidemiological study of Chinese, Malaysians, and Indians and Pakistanis, all of whom were Singapore national servicemen, was reported by Dr. F. McCombie, director, division of preventive dentistry, Health Branch, Government of British Columbia, Victoria.

Eleven dentists, McCombie said, examined 196 Chinese, 180 Malaysians, and 73 Indians and Pakistanis with a mean age of 21.4 years. The Chinese demonstrated a DMF rate of 13.3, the Malaysians 8.4, and the Indians and Pakistanis 8.0.

In attempting to explain the difference between the Chinese and the others, McCombie investigated the extent to which each group practiced oral hygiene and chewed Betel nuts, and also observed periodontal disease status and the attrition to their teeth. Although significant differences were found among the groups with respect to these factors, none of the findings explained the higher DMF rate of the Chinese.

In a concurrent study of the mean fluoride content of enamel in teeth of representatives of the three groups in Singapore, McCombie found that the mean fluoride content in enamel in Chinese (average age 20.7 years) was 20.1 ppm, whereas in Indians, Pakistanis, and Malaysians (average age 22.6 years) the mean was 135.8 ppm.

The differences, McCombie observed, between the average fluoride concentrations in the enamel are considered as most likely reflecting the major cause of the differences

between the DMF rates for these groups, the major cause likely being an increased fluoride concentration in the outer enamel.

Since the water supply on the island of Singapore had a fluoride content of less than 0.2 ppm prior to controlled fluoridation which began in 1956, foods are currently being studied for fluoride content to explain the differences among the groups studied, McCombie said.

Grants-in-Aid Boost Welfare Dental Care

In a broad scanning of developments in State welfare dental services, Azile H. Aaron, regional representative in San Francisco, Bureau of Public Assistance, Social Security Administration, described the nationwide lack of adequate dental care for children in State agencies before 1956. That year the Social Security Act was amended to give separate and added matching funds for medical care.

She commended the prepaid dental contract for statewide welfare services pioneered in the State of Washington in June 1953, in which roughly 22,000 persons, or 20 percent of those eligible, are served yearly. Although the plan does not give complete dental care, Aaron reported that it is providing statistics useful for further legislation.

The dental care project in California was described as the largest and, for children, the widest in scope. Most of the \$2¼ million earmarked in State funds and matched by Federal money is for complete dental care of the 77,000 children, ages 7 through 12 years, in the aid to needy children program. So far, 21 percent of the eligibles, or 1,500 each month, have been treated, with average cost of about \$76. Other recipients receive care only for acute or emergent conditions.

Emphasizing that public assistance aims at providing a minimum living standard for those who, for reasons beyond their control, cannot

progress goes on in the other countries.

Fish catches are swelled by mechanization of fishing craft and by introduction of new types of nets. But in many countries, even where the population needs protein foods, there may be little demand for fish, and FAO has given help with this problem in Chile, Yugoslavia, and Mexico. Handling and transport facilities of the country often are such that fish cannot be shipped inland without spoiling.

Kwashiorkor is a serious syndrome occurring in infants and young children whose diet after weaning does not contain enough protein. Since 1950, FAO, WHO, and UNICEF have been cooperating in a campaign against the disease. The three organizations also cooperate in setting up short training courses for nutrition personnel in member countries. FAO fellowships are awarded for study abroad.

Old Soldiers Never Diet

According to the Army basic standard, the minimum nutrient intake of the physically active soldier in areas of temperate climate should be 3,600 calories, while for troops engaged in outdoor activities where the prevailing temperature is sub-zero, the minimum should be 4,400 calories.

Dr. Theodore E. Friedemann, Dr. Herman F. Kraybill, and C. Frank Consolazio, U.S. Army Medical Research and Nutrition Laboratory, Fitzsimons Army Hospital, Denver, Colo., described the Army dietary.

The feeding of U.S. Army personnel is planned in accordance with minimal dietary standards based on the recommended allowances of the National Research Council and modified by special requirements of troops under operational conditions, they reported.

Since 1941 the procurement and serving of food to Army personnel has been prescribed in a master

menu, published 6 months in advance and used Army-wide. The menu is planned to yield the basic standard nutrients after making a 15 percent allowance for edible waste. During 1957 the average total nutrients provided by the master menu were 4,195 calories, 131 gm. protein, 199 gm. fat, and 470 gm. carbohydrate. The vitamins and minerals in the menu are well above the levels recommended by the National Research Council.

In surveys conducted in four basic training camps, the average of nutrients the soldier consumed in the mess, at the post exchange, and from other sources was 4,265 calories, 131

gm. protein, 201 gm. fat, and 484 gm. carbohydrate. These results agree rather closely with the total edible nutrients provided by the master menu.

A review of military nutrition since colonial days shows that rations have undergone their most rapid changes since 1890, the authors stated. The main reasons for this, they said, have been acceptance of scientific advances in nutrition, altered conditions of warfare, growth of national and individual wealth, expanding production of certain foods, improved storage methods, and extension of transportation and distribution facilities.

School Health . . .

Some Facts of Life Not Widely Known

That the public is not adequately informed about human reproduction was concluded from a survey of high school and college students and adults in a wide range of socioeconomic groups.

Dr. H. Frederick Kilander, professor of education at New York University, who reported the findings, cited the response pattern for the question, "Can a prospective mother make her child more musical if she listens to good music?" Correct answers ranged from a low of 20 percent for a junior high school class to 80 percent for a group of teachers.

The two tests given were part of a larger study, begun in 1935. The Kilander health knowledge test, with 100 multiple-choice items including 10 on sex education, was given to 200 groups of high school and college students and adults. And the information test on human reproduction, consisting of 33 multiple-choice questions, all on human reproduction, was administered to 15 college and adult groups.

Kilander said that about half of the high school students, 3 out of 4 of the college students, and 8 out of 10 of the adults knew that the premarital blood test required in many States was for detecting syphilis, rather than gonorrhea, tuberculosis, or hemophilia.

On the whole, there has been a slight but continuous rise in the level of information during the past 25 years, with college students tending to improve more than high school students during the period.

Adult groups without education beyond high school or without college biological or health instruction tend to score below today's college freshmen, Kilander said. Young parents with high school and college education are better informed in sex education, have a more wholesome attitude toward the subject, and are more successful in presenting it to their children than their counterparts were a generation ago.

The tests also brought out that male high school and college students tend to be slightly better informed on questions about the female sex than the female students are about males. Male students also tend to know more about the anat-

commodities can justify capital investment for sterilization by radiation.

From present accomplishments, Clifton concluded, it appears that the treatment of food by radiation will be used first in combination with other types of treatment, complementing rather than replacing the present conventional processes such as canning, refrigeration, dehydration, and antibiotics.

Advises Caution In Diet Appraisal

The recommended dietary allowances of the National Research Council, which were first presented at the National Nutrition Conference in 1941, are a valuable tool in making dietary studies and in food planning, said Dr. Esther F. Phipard, Household Economics Research Division, Agricultural Research Service, U.S. Department of Agriculture.

In studies of the diets of individuals, use of the recommended dietary allowances as a point of reference in analysis and interpretation provides a basis for qualitative evaluation of the individual's diet, and also facilitates comparison of diets of persons with different nutritional needs. Furthermore, averages per nutrition unit for different families or even for different population groups are directly comparable, provided the same dietary allowances and scale of relatives were used in their derivation.

The words used to describe or interpret dietary evaluations are extremely important, she said. To state that the nutrients provided by a diet meet, exceed, or fall short of the recommended dietary allowances or some proportion of them, she observed, is a factual statement based on calculations in which the allowance was used as a point of reference. On the other hand, description of diets as adequate or inadequate requires careful qualification. She deplored the fact that the rec-

ommended allowances have sometimes been treated as if they were precise, almost magic figures, as if to imply that any diet supplying less than the levels recommended in them indicates malnutrition. Such implications she said, have been seized upon eagerly by promoters of certain food supplements and other dietary nostrums.

Another use of the dietary allowances mentioned is in developing weighted per capita allowances to be used as a guide in planning food supplies for a country or any large population group, or for comparison with estimates of the nutrients available from the per capita food supply.

Caution is needed, Phipard advised, in drawing conclusions from these comparisons. Nutrient levels recommended in the dietary allowances refer to amounts to be ingested, whereas the nutrients calculated to be in diets or in food supplies may include quantities lost or discarded in distribution or in preparation for eating. Thus, the two sets of data may not be directly comparable.

Intelligent use of the recommended dietary allowances necessitates study of the text which accompanies them in order to understand how they were developed and what they stand for, she emphasized. They are designed for the maintenance of good nutrition in healthy persons, and they are subject to change from time to time as nutritional knowledge advances.

Says Hungry Nations Must Grow Food

Underfed nations must grow more of their own food, asserted Jean W. McNaughton, regional nutrition officer, Food and Agricultural Organization of the United Nations.

However well they are taught the principles of nutrition, McNaughton said, people cannot feed themselves properly unless the essential nutrients are available at a price they can afford. The nutritionist and the

agricultural economist must work together in long-term agricultural programs to cope with malnutrition, she said.

The task of the Food and Agricultural Organization is to raise levels of nutrition and to help improve the production and distribution of food and agricultural products in member countries. Following are some of the FAO accomplishments described by McNaughton.

Lack of accurate, up-to-date information in every branch of agriculture and nutrition is one of the most serious handicaps to planning. FAO is helping set up or improve agricultural statistical services. It also supplies experts to train personnel of the country in dietary survey work. FAO committees on calorie and protein requirements have made recommendations which have been adopted by many countries.

Systems of land tenure, which affect some of the agriculturally advanced countries as well as those less fully developed, are frequently at the root of the food shortage. FAO has sponsored three regional centers for the exchange of ideas and experience about land use. The first center was in Brazil in 1953 for countries of Latin America, the second in Bangkok for the Far East, and the third in Iraq, attended by 12 Near East countries.

Improved types of seeds and livestock have been introduced into member countries. On the other hand, control of animal diseases is slow work. Owners of livestock have to be persuaded that diseases can be controlled. An example is the experience with rinderpest, for many years the greatest killer disease of livestock in Africa and Asia. The earliest FAO campaigns against it were in Ethiopia, Thailand, and Afghanistan. At first farmers hid themselves and their cattle when the vaccinators appeared. Not until vaccinations began to produce demonstrable results were the farmers converted. Now Afghanistan has been almost cleared of rinderpest and

minimum requirement and that more frequent reviews are preferable.

In 38 percent of the communities replying, review teams held personal interviews with the child and his family; 35 percent of communities did not provide such teams; and 27 percent did not answer the question. While recognizing differences of opinion as to the value of personal interviews, Starr and Wallace stated that considerable inappropriate educational placement occurs unless the child is seen by the reviewers.

In the 98 cities, such community facilities as a crippled children's clinic were rarely used in evaluating handicapped children. When well-developed evaluation and diagnostic services exist, it would be easier for the school system to use them than to attempt to duplicate them, the authors stated.

Orinda Study Favors Clinical Eye Test

The modified clinical technique was found superior to other methods of visual screening in cost and efficiency, during the longitudinal Orinda study which tested the vision of 1,000 elementary school children in California during 1954 through 1956.

The study, partly supported by U.S. Children's Bureau funds, was reported by Dr. Henrik L. Blum, health officer of Contra Costa County, Calif.; Dr. Henry B. Peters, associate clinical professor of optometry, and Dr. Frank Johuson, clinical instructor of optometry, University of California School of Optometry; and Dr. Jerome W. Bettman, professor of surgery (ophthalmology), and Dr. Victor Fellows, Jr., clinical instructor of surgery (ophthalmology), Stanford University Medical School.

During the study period, they observed, the proportion of children found to have visual defects rose about 1.6 percent per year with age. Children with such problems in age groups 5, 6, and 7 years amounted

to 18 percent, increasing to 31 percent in age groups 13, 14, and 15. Also noted was a large shift toward more myopia by those already myopic and a trend toward myopia among some normal children. Only one-seventh of those referred to physicians had uncorrectable defects.

Blum and associates stressed harmonizing opinions and consolidating standards of local physicians for successful visual screening.

Outstanding recommendations were:

- The screening program in the community's elementary schools should be developed by a steering committee of public health and school representatives, ophthalmologists, optometrists, and parents.

- The modified clinical technique should be given all first-grade children and new entrants by a qualified professional examiner. Those passing should have annual Snellen tests.

- School health education should include formal work in visual health, designed also for parents' interest.

They described the county health department, which gives consulting services to schools and has faculty members of participating universities, as a coordinator and promoter of the research.

School Health System Studied in Brookline

A study of the school health program in Brookline, Mass., which in 1955 shifted control of services from the school system exclusively to direction jointly with the health department, was reported by Dr. Marjorie A. C. Young, coordinator of the study, and Dr. Leon J. Taubenhans, director of public health.

One objective was to define and describe the functions of employees in the school health program. Initially, baseline data on school health policies and practices were gathered by Dr. Young through interviews

and from records in the school system and health department. From these data, profiles of each of the eight elementary schools and of the whole system will be formed for comparison. Each profile will cover services, environment, instruction, and administration.

Interview questions were carefully designed, pretested, and revised to describe actual policies and practices without judgmental or value connotations. About 1 week was spent in each school. Persons interviewed numbered 121 out of a total of 335. They included all principals, school nurses, and chief custodians, as well as a 30 percent stratified random sample of all other full-time school personnel. Initial tabulation of the data have been completed, they said.

Among the side benefits from the study mentioned by Young and Taubenhans, was the growing interchange of aid and ideas between school authorities and the health staff, reaching out into other community fields, such as the glaucoma screening program.

Sometime after 1960, they concluded, the interviews will be repeated to determine the extent and direction of change.

Many Reading Failures Of Nonvisual Origin

After examining more than 700 intelligent children with reading disability, Dr. George E. Park of the department of ophthalmology, Northwestern University, reported that only 19 percent needed spectacles.

The complex factors of the disability in mentally unimpaired children called dyslexia, are physical, psychological, social, and educational. In Park's opinion, the handicaps can be corrected in approximately 85 percent of the cases.

About four times as many boys have reading failure as girls, he said, speculating that this condition may express blocked sublimation of aggressiveness, notably stronger in boys.

only and physiology of their own sex than females about theirs.

Kilander asserted that facts of human reproduction should be integrated into education for family living and into sex education to prepare for marriage and parenthood and to combat socially undesirable behavior.

School Services Needed By Handicapped Children

School systems should provide more educational services for some types of handicapped children and should make more use of medical specialists and health department and community facilities to evaluate these children, suggested Dr. Helen M. Wallace, University of Minnesota School of Public Health, and Dr. Helen M. Starr, Minneapolis Board of Education.

From the replies to questionnaires concerning the educational services available to handicapped children in 98 of the 100 cities of more than 100,000 population, the authors found that all 98 school systems provide for children with orthopedic, neuromuscular, or neurological conditions and for mentally retarded children. Ninety-six percent of the school systems provide for children with speech difficulty, 95 percent for the hard of hearing, 94 percent for the partially sighted, and 91 percent for children with rheumatic fever or heart disease. However, children with epilepsy or cleft palate and those who are emotionally disturbed, deaf, or blind, are less frequently provided for.

Wallace and Starr felt that the policy of admitting children under 5 years of age to public schools, which may benefit certain types of handicapped children, should be extended to the deaf, blind, hard of hearing, partially sighted, and certain groups of those with orthopedic, neuromuscular, or neurological conditions. Less than half the systems responding admitted younger children with these handicaps.

The questionnaires revealed that admission criteria for retarded children varied considerably, with required I.Q. levels ranging from 20 to 50-75. Other factors, such as social adjustment, should also be taken into consideration.

Placement

The number of children in each of the various types of educational placement reported by the responding school systems is shown in the table. Schooling in hospitals and convalescent homes is confined mostly to the orthopedic group, and home instruction, to the orthopedic, rheumatic fever, and cardiac disease groups. Residential schools are used primarily for the orthopedic, deaf, and emotionally disturbed groups of children.

Ideally, according to the authors, all public school systems in the larger urban areas would provide for all types of handicapped children in regular class and special day class. Home instruction, special day school, and instruction in hospitals and convalescent homes would be reserved for certain children for relatively brief periods.

Admission and Review

Most of the communities reported having criteria for the admission of handicapped children to the public

school systems. However, members of the various professional disciplines participated in establishing criteria in only 18 communities, and medical personnel were participants in only 7 communities. The authors suggested the participation of members of the health and welfare departments, vocational counselors, and social workers in setting criteria.

Wallace and Starr felt the health department should also participate in the review of applications for educational placement. In half the school systems, applications were reviewed only by the board of education, never by the health department alone, and only in one-fifth of the systems was review a joint function of the education and health departments.

A team reviewed applications in most communities; its members most frequently were a psychologist and a school administrator. The authors advocated greater use of nurses, teachers, school counselors, vocational counselors, and medical specialists such as cardiologists, pediatricians, ophthalmologists, otologists, and orthopedists.

The authors also saw a need for periodic review of placement and review prior to withdrawal from placement. They held that a yearly review of each handicapped child regardless of type of placement is a

interests, and maintenance of consistent behavior standards.

Recommendations

Among the conference recommendations were:

- Preparation of a State curriculum guide for health education at all school grades.
- Availability of health consultants on the district level to assist in improving health instruction.
- A careful, periodic reexamination of health instruction programs for teachers, especially regarding effective use of contributions from the several disciplines and from State, county, and community health agencies. The same holds for school agendas in health.
- Setting up organized methods

for the constant, smooth absorption of new information and materials in school and teacher education programs.

- Careful planning of inservice education of teachers, so that they grow after teaching begins, under the leadership of principals and superintendents.

- A meeting, at least once a year, of representatives from teacher training colleges, the schools, and State health and education agencies, to consider teacher preparation for health instruction.

Finally, the need for health instruction courses for college faculty members was underscored, Vavra reported, remarking that the University of Washington is working toward a master's degree in health education.

respect, but it will help to decide the treatment for the disease, he said.

Study Death Certificates For Accident Data

Local health departments may analyze death certificates for clues to accident prevention, asserted Albert P. Iskrant, chief of operational research, Accident Prevention Program, Public Health Service.

While he did not propose restricting epidemiological investigations of accidents solely to fatal accidents, he noted that approximately 100,000 deaths are caused by accidents each year and the data are available for analysis.

Study of death certificates reveals information about the age, sex, race, marital status, and physical condition of the accident victims, the agent causing the accident, and the environmental factors associated with fatalities. Epidemiological investigations need not be limited to these data but can be carried into many facets of the host, agent, environment, and their interaction, Iskrant stated.

Describes Characteristics Of Childhood Accidents

Accidents, as the leading cause of death among children, have not risen to the top of the list but rather have been uncovered, stated Dr. James L. Goddard, chief, Accident Prevention Program, Public Health Service.

He pointed out that in the last 55 years mortality due to contagious diseases dropped so phenomenally that improvement in accident fatality rates is scarcely noticeable. However, some 17 million children sustain accidental injuries in the United States each year, according to estimates based on the first 6 months of the National Health Survey, Goddard added.

He drew a profile of accidents

Safety . . .

Local Sources Can Supply Accident Statistics

Existing indicators of local accident morbidity and mortality should be examined before a health department undertakes door-to-door studies, declared Dr. Charles M. Cameron, Jr., associate professor, School of Public Health, University of North Carolina, and safety consultant, North Carolina State Board of Health.

He questioned whether elaborate house-to-house surveys to obtain data on a community are necessary, especially in view of the health departments' shortages of funds and personnel and the difficulties of obtaining reliable, comprehensive information.

Cameron listed some sources of data in many communities. Within the health department, much useful information may be gleaned from death certificates, crippled children's clinics, school health programs, housing inspection records, and

records compiled by nurses, sanitarians, and other staff members who routinely visit homes.

Other local sources of useful data include hospitals, fire departments, emergency squads, schools, industries, health insurance organizations, agricultural extension programs, and safety councils, agencies which have an interest in home or farm safety. Often, with some slight modification in record processing or tabulation, such data can contribute to the health department's accident statistics.

After describing some techniques developed in surveying accident morbidity, Cameron pointed out that these fact-finding activities require specialized skills and personnel not always found within the local health department.

For the average health department seeking to make a community diagnosis of home and farm accidents, tapping local resources should be the first step. The resulting statistical and epidemiological information may not be complete in every

Among medical factors, Park mentioned the importance of the thyroid gland in mental functioning in children. Twenty-seven percent of those in the study had hypothyroidism and 4 percent hyperthyroidism to a degree that therapy was indicated. Reflexes in 15 percent were decreased and 11 percent were exaggerated. Choreic symptoms were present in 6 percent.

Although half the children had borderline or mildly abnormal electroencephalogram records, none were severely abnormal. He cautioned that care must be used in interpreting these data, since such records occasionally obtain for normal children. Bone maturation studies showed 8 percent were retarded in growth for their age. Correlating blood counts of 200 of the children revealed a 27 percent neutropenia, said Park.

Stressing the link between hearing and language function, he remarked that 14 percent of the patients had had abscessed ears. Also, 9 percent had learned to talk late.

Enuresis, with an 18 percent incidence among the children, usually is coincident with other symptoms of personality disturbance that almost always occur in dyslexic children. Even with enuresis and other disturbances present, causes of reading failure may not be pinpointed alone in conditions causing emotional stress.

Though occasionally dyslexia occurs in successive generations, Park believes that the characteristic is imposed usually by experience and very rarely by genetic factors.

Eye Defects Screened Before School Age

Neglect of preschool children with eye defects was criticized by Florence Cunningham, nurse consultant of the National Society for the Prevention of Blindness, New York City. Such neglect is especially serious for children with amblyopia, she said, because full correction may hinge on

the start of treatment before age 6.

Following a detailed description of screening criteria and methods, Cunningham cited results of three mass screening projects in which the groups sent to physicians for eye care were, respectively, 85, 88, and 100 percent correct referrals.

Regarding current disbelief in the successful screening of children so young, she pointed out that a project in Schenectady, N.Y., has screened 60 percent of children in the 3 to 3½ year group, 74 percent from 3½ to 4, and 96 percent of 4-year-olds.

In different communities screening has started with the children of those attending adult education classes, at well-child conferences, in housing projects, and by letters to parents through the schools. The average referral rate for all children screened has been between 5 and 6 percent.

Public Schools Can Help Pupils With Eye Defects

Barely 11 percent of the estimated 78,000 partially seeing children in our public schools were receiving special help in late 1957. This was brought out by Dorothy Bryan, assistant director of special education of the blind and partially seeing, Illinois Department of Public Instruction, in a discussion of current approaches to teaching such children.

Rather than segregate such pupils in special schools or classes, she would enroll them in regular grades in public schools and provide special teaching only for activities needing close, intensive vision. Sometimes such aid is provided by an itinerant specialist.

In Bryan's opinion, the child can thus establish his school social status and, if his vision improves, return full time to regular classes.

Some States, such as Illinois, she said, offer guidance to teachers in schools unequipped for special services, dealing with each case individually. Large-type books and

reimbursement for reader service are given.

She pointed out that these services had secondary value in providing a healthful school environment, such as proper lighting, well-printed books, and correctly designed seats.

Teacher Health Education Scanned in Washington

Schools must instill in today's children firm knowledge and interest in personal and community health, if rapid advances in medicine in the future are to be translated into good health practice.

This theme of a conference on preparing teachers for health instruction, held in Seattle, Wash., during March 1958, was reported by Catherine Vavra, health educator and lecturer with the University of Washington in Seattle. Most of the 47 participants were engaged in teacher education and represented 14 State and private colleges and universities in Washington.

Results of a questionnaire, Vavra said, showed that 13 of the responding 14 institutions offer prospective teachers a course in personal health, and 11, an added course in health instruction. Only 4 of these teacher education institutions require a school health course, although another 7 offer such a course as an elective. Only two have a faculty-student health council.

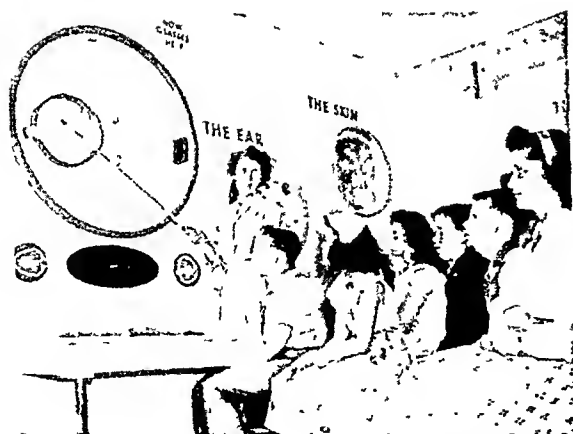

The School's Role

Conferees agreed that health and safety instruction in the school is not an end in itself but rather a bridge to a full life. This teaching must have a safe school environment and a program which helps the child shoulder responsibility for his own health and safety.

Included in the definition of a sound school environment, said Vavra, was a rich social-emotional atmosphere, with the teacher's awareness of individual differences and personality adjustments among the children, enthusiasm for their

Hinsdale Health Museum

*an Illinois community
takes a dynamic approach
to health education*

(David Lannes photo)

A biology teacher on the museum staff explains to young visitors the exhibit showing normal and abnormal eyesight and correction of faulty vision. The museum usually conducts at least two such classes daily.

Dedicated to the promotion of better living through health education, 13 exhibits on the human body formed the opening show of the health museum in Hinsdale, Ill., in May 1958. The museum is housed in a wing of the Hinsdale Medical Center, founded by the Kettering Family Foundation of Chicago. About 34,000 persons visited the museum during the first 6 months.

Pushbuttons, telephones, flashing lights, and moving parts encourage visitor participation. Most of the exhibits focus on a single component of the body, such as the brain, the ear, and the eye.

among those under 15 years of age. Thirty percent of the nonfatal accidents and 15 percent of the fatal accidents occur in this age group. Motor vehicle accidents cause 30 percent of these fatalities, drowning 13 percent. Boys have twice as many accidents as girls.

Accidents occur predominantly in the home, reach a seasonal peak in July and August and a low in February and March, and injuries are most frequently lacerations and head injuries. Burns and scalds are an appreciable proportion of all primary injuries only among those under 1 year of age.

Goddard cited the 200 poison control centers set up in the United States during the last 5 years as an example of current efforts to reduce childhood accident hazards.

Hospital Data on Injured Spur Preventive Measures

Selected data on 15,272 patients treated for trauma in 15 municipal general hospitals during 6 alternate months of 1957 were reviewed by Dr. Marta Fraenkel, medical program evaluation officer, New York City Department of Hospitals.

Indicating the clinical seriousness of their injuries, Fraenkel stated that 656 patients died in the hospital; of these, 224 died within 48 hours after admission. Nearly 6,000 patients required hospitalization of more than a week; 1,700 of these stayed more than a month.

The data, extracted from medical charts of the traumatic patients, were processed centrally as part of

a project called the hospital morbidity reporting system. Such data, Fraenkel said, provide substantial information on the incidence of various injuries among people of given age and sex as well as on the amount of hospital care needed. She stressed the desirability of including information on the external cause of injury, which at present is not specifically recorded.

Trauma due to accidents, poisoning, or violence was the leading nonobstetrical cause for hospitalization. Traumatic patients, representing nearly 13 percent of all discharges and 16 percent of all nonobstetrical discharges, received a total of 239,000 days of inpatient care during the 6 months of the study.

More than 62 percent, 9,516, of the traumatic patients were male. Approximately 44 percent of the total and 55 percent of the nonobstetrical hospital patients were male. Of the traumatic patients under 15 years of age, two-thirds were boys. The excess of male patients did not subside until age 65.

Fractures were the leading type of injury; there were 5,506 fracture patients, an average of 30 admissions per day. Other numerically significant injuries were brain concussions, open wounds and lacerations, and poisonings. Least significant numerically were "superficial," head, and internal injuries, dislocations, and burns.

Variations by Age

Of 3,275 traumatic patients under 15 years of age, 39 percent were under 5 years; 34 percent, 5-9 years; and 27 percent, 10-14 years. This

group comprised 20 percent of all children admitted. In the 5-9 age bracket, injuries accounted for nearly 28 percent of all admissions; a third of the boys admitted in this age group were traumatic.

Among children, the most significant injuries were brain concussions, fractures of the extremities, open wounds and lacerations, superficial injuries, and poisonings. Noteworthy for their relative prevalence among children, Fraenkel remarked, were foreign bodies in the digestive tract, aspirin poisoning, and lead poisoning.

High incidence of injuries among children has prompted a study to analyze the relationship between external cause and nature of the injuries.

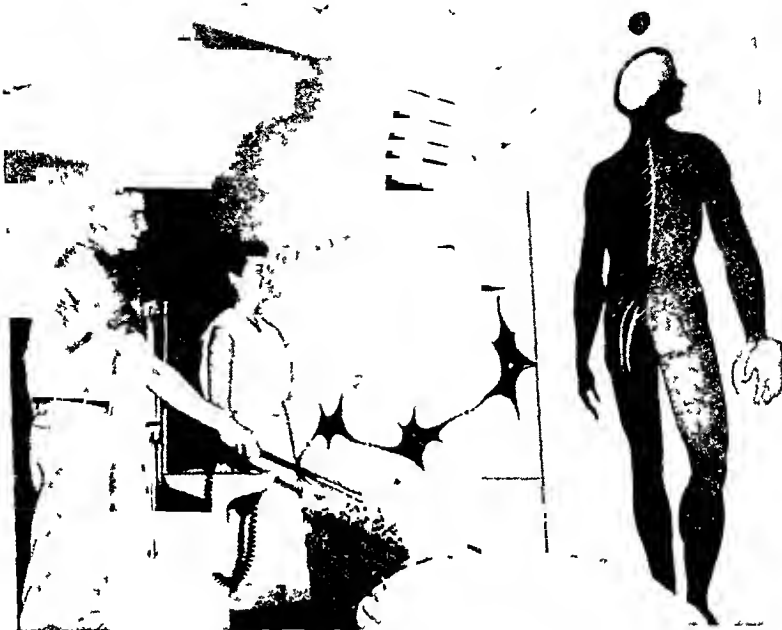

Nearly 15 percent, 2,262, of all traumatic patients were 65 or over. Fractures, almost half of which were of the femur, accounted for 60 percent of all traumatic conditions in this age group, against 32 percent of patients under 65 years.

More than 100 aged patients are admitted monthly to the municipal general hospitals for hip fractures. This figure is particularly significant, Fraenkel pointed out, because of the length of hospital care required by such patients and because of the protracted, or even permanent, physical impairment that may result. Some conditions, she said, which are frequent among young people are of relatively little significance among the aged; for example, among those 65 or over, there were only 36 admissions for burns and only 18 for foreign bodies in the digestive tract.

Engineers to Discuss Air Pollution

The continuing challenge of air pollution is the theme of a meeting of the American Society of Mechanical Engineers, Pittsburgh Section, at the Penn-Sheraton Hotel, April 20-21, 1959. All public health workers are invited, to share in Pittsburgh's bicentennial celebration.

Students operate the control on a giant brain, especially constructed for Hinsdale. The unit presents what is known about the nature of nervous energy and thought processes.

(Chicago Tribune photo)

(Stephen Heiser photo)

The comprehensive heart display shows both inside and outside of the organ, circulation, heartbeat, and an electrocardiogram.

Other displays describe the body's structural systems, birth, and the coughing process. A transparent female figure, life size, in Plexiglas, contains organs and systems in distinctive colors, which are lighted as a voice on a synchronized sound track explains their functions. (A similar exhibit, pictured in *Public Health Reports*, March 1958, is installed in the Smithsonian Institution.)

The center's museum, health theater equipped with a film collection, and medical library are free to the public; they are maintained by the proceeds from rentals on medical center offices.

The museum schedule calls for close collaboration with schools in the area and with the physicians in the medical center.

(Rus Arnold photo)

"You began as a single cell . . ." says the voice recounting the engrossing story of body cells. Designed especially for Hinsdale, the exhibit forms the museum's central motif.

Part of the exhibit on the structural systems is a skeleton that moves (right). A neighboring model is a male figure with muscles exposed.

HEARING AND BALANCE

(Rus Arnold photo)

The phenomenon of hearing is demonstrated by means of a human "telephone receiver."

A favorable milieu for the growth of staphylococcal enterotoxins in codfish may be created by extensive handling, use of certain salt concentrations, and long immersion in tapwater before cooking.

Two Poisoning Outbreaks in Puerto Rico From Salt Preserved Codfish

ALFONSE T. MASI, M.D., RAFAEL A. TIMOTHEE, M.D., M.S.P.H., ROLANDO ARMIGO, M.D., M.P.H., DARWIN ALONSO, Ph.D., and LUIS E. MAINARDI, M.D.

IN THE FALL of 1957 Puerto Rican health authorities investigated a mass outbreak of food poisoning at the Ponce District Hospital and another at the institution for juvenile delinquents of San Juan. Both events were presumably caused by staphylococcal enterotoxins involving a common vehicle—salt-preserved codfish (Atlantic). The food in this form had not previously been incriminated in such intoxications.

The incident at the hospital, involving a

reported 303 patients in a total population of 457, occurred following lunch on September 5, 1957. There were no reports of acute gastroenteritis in the community outside the hospital. In the juvenile institution, the outbreak followed lunch on November 27, 1957, affecting 236 inmates out of a total of 320. Both outbreaks were first reported to local public health authorities, who in turn informed the bureau of communicable disease control in the Puerto Rico Department of Health.

Dr. Masi is an epidemiological intelligence officer of the Communicable Disease Center, Public Health Service. Dr. Timothee is chief of the bureau of communicable disease control, Puerto Rico Department of Health, where Dr. Mainardi serves as associate epidemiologist. Dr. Armijo is associate professor of epidemiology, and Dr. Alonso, assistant professor of bacteriology in the University of Puerto Rico.

Dr. Milton J. Foter of the Robert A. Taft Sanitary Engineering Center provided technical assistance, and Dolores Lugo Danielsen and Dr. Elaine Updyke of the Communicable Disease Center contributed to laboratory phases of the study. The paper was presented in essentially the same form before the Epidemic Intelligence Service Conference at the Communicable Disease Center in Atlanta, Ga., May 16, 1958.

Ponce District Hospital Outbreak

Between the lunch at the Ponce District Hospital and the onset of illness, the mean duration of time was $3\frac{1}{4}$ hours, with a range of 1 to 15 hours. The onset was sudden, with vomiting, headache, and abdominal pain but no significant temperature change. The majority had diarrhea, and several noted mucus in the discharge.

The mean duration of illness was $6\frac{1}{4}$ hours, with a range of 2 to 24 hours. An associated fatality occurred in a chronically ill 53-year-old woman with long-standing pemphigus vulgaris, in whom postmortem examination revealed changes of the intestine compatible with acute inflammation.

The menu for the suspected lunch consisted

Federal programs for older people (excluding programs of the Department of Health, Education, and Welfare) are summarized in Issue No. 77 of the Social Legislation Information Service, Washington, D. C.

pyogenes var. *aureus* was readily demonstrated in both specimens in the approximate concentration of 10^6 organisms per gram. This strain was subsequently encountered by the food bacteriology section of the department and has been confirmed as such by the Staphylococcal Unit of the Communicable Disease Center, which undertook phage typing of strains isolated in the outbreaks.

No cultural examination of the kitchen personnel was made for staphylococcal carriers because of the original lack of success in isolating this organism from the food. There was, however, no evidence of superficial purulent lesions or a history of recent upper respiratory infection.

Outbreak at the Juvenile Institution

In the outbreak at the institution for juvenile delinquents, the mean interval between lunch and the onset of illness was slightly less than 2 hours, with a range of several minutes to 8 hours. The symptoms were similar to those of the previous outbreak, and the duration of illness was less than 24 hours in two-thirds of the cases and from 1 to 4 days in the remainder.

The menu consisted of codfish salad, rice and beans, bread pudding, and bread. An analysis of attack rates of illness by food consumed by 223 available inmates (table 3) strongly implicates codfish salad as the responsible item ($P < .0001$). Furthermore, an analysis of attack rates by food combinations reveals an absence of illness in inmates consuming either rice and beans or pudding but abstaining from the salad (table 4).

The preparation of codfish salad at this institution left no doubt as to its potentialities to

Table 4. Rate of attack of acute gastroenteritis among persons eating certain food combinations for lunch at the institution for delinquents, November 27, 1957

support the production of enterotoxin. Food for the inmates is prepared in a separate kitchen, which is of substandard hygiene and is staffed by the inmates. At 3:00 p.m. in the afternoon, 20 hours before serving, 100 pounds of cod were boiled for 1 hour. Fresh tapwater was added to the caldron and three inmates extracted fish by hand to remove bones. At 5:30 p.m., with one-quarter deboned, the work was abandoned to be completed the following morning. The fish remained at room temperature until 11:30 a.m., when it was served after light seasoning.

No specimens were obtained from patients. The food bacteriology section isolated various strains of *Staphylococcus pyogenes* from the rice and bread pudding but could not demonstrate any such contamination in the salad. However, the school of medicine isolated a coagulase-positive strain of *Staphylococcus*

Table 3. Rate of attack of acute gastroenteritis among persons eating lunch at the institution for delinquents, November 27, 1957

Food item	Persons eating food item			Persons not eating food item		
	Total number	Number ill	Percent ill	Total number	Number ill	Percent ill
Rice and beans.....	221	177	80.1	2	2	100.0
Pudding.....	194	159	81.5	29	20	69.0
Codfish salad.....	205	179	87.3	18	0	0
Bread.....	202	165	81.7	21	14	66.7

of codfish salad, tomatoes, starchy fruits and vegetables (plantains, yams, and sweet potatoes), bread, butter, whole milk, and guava paste. Each item was investigated as to manner of preparation, and an analysis of attack rates of illness was made with the result that all could be reasonably excluded as responsible vehicles with the exception of codfish salad (table 1).

Because of the small number of persons in the originally interviewed group that had abstained from codfish, all inpatients were questioned in an effort to include cardiac and diabetic patients who were served the same menu with the exception of codfish salad and guava paste. Only guava paste was included as a control food to expedite this second survey which covered 196 patients (table 2).

The high attack rate of gastroenteritis (79.2 percent) in patients eating codfish salad without guava paste and the absence of illness in 37 cardiac and diabetic patients who abstained from the salad strongly implicates codfish as the responsible item ($P < .0001$). The only cardiac patient who suffered symptoms admitted eating cod against dietary orders.

The entire hospital population is served from the single kitchen in which sanitation was found to be impeccable. The routine manner of preparing codfish salad was to allow whole fillets to desalt in cold tapwater for 12 hours during the night and to prepare the salad on the morning of serving. However, a significant modification in technique occurred on the morning prior to the outbreak, when the salted fish was

Table 2. Rate of attack of acute gastroenteritis among 196 patients eating certain food combinations for lunch at the Ponce District Hospital, September 5, 1957

Food combinations	Total persons	Number ill	Percent ill
Codfish salad, with guava paste	133	120	90.2
No codfish salad or guava paste	37	0	0
Codfish salad, no guava paste	24	19	79.2
Guava paste, no codfish salad	2	0	0

erroneously placed in hot tapwater. The average temperature of the kitchen is 100° F. during the day and 72° F. from 7 p.m. to 7 a.m. On the following morning the cod was prepared as a salad and distributed into thermatically controlled serving cars maintaining a temperature of 165° F. The food remained in these vehicles for 60 to 90 minutes before being consumed by the hospital population.

Five vomitus, two stool, and three blood cultures of severely ill patients revealed no staphylococci or other pathogens. The food bacteriology section of the health department could demonstrate no pathogens in any of the food items after considerable effort. Two frozen samples of cod were referred to the bacteriology department of the University of Puerto Rico Medical School after several weeks, because of the epidemiological implication. There, a coagulase-negative strain of *Staphylococcus*

Table 1. Rate of attack of acute gastroenteritis among persons eating lunch, Ponce District Hospital, September 5, 1957

Food item	Persons eating food item			Persons not eating food item

preserving codfish is pertinent to an understanding of the food's potentialities for contamination with enterotoxigenic staphylococci. The flesh and body cavities of salt water fish are sterile (11), but the surfaces and gut may be contaminated in the order of 10^2 to 10^7 . Dyer has demonstrated that 73 percent of aerobic flora of Atlantic cod may belong to the micrococcus group and that 7 percent of these were *Staphylococcus pyogenes* vars. *aureus* and *albus* (12). However, these organisms appeared to be marine in origin (13) and were not considered potentially pathogenic because of a uniformly negative coagulase reaction (14). When the fish arrives at shore and is handled, the micrococcus flora increases in inverse ratio to the degree of cleanliness of the premises (15). Of the micrococci growing at 98.6° F., 10 to 16 percent were shown to be indistinguishable from coagulase-positive *Staphylococcus pyogenes* var. *aureus*. These micrococci must be considered potentially pathogenic (16).

After filleting, the cod is preserved with salt which appears to be a complex process involving the inactivation of bacterial enzymes besides the withdrawal of moisture, thus restricting microbiological activity (17). Salt is interspersed between layers of split fish, establishing a concentration of about 20 percent in 14 to 16 days while the juices are allowed to run away, with a maximum loss of weight of 30 percent (18). The flesh, at this stage "wet stack" or "green" cured, always contains some microorganisms, almost exclusively micrococci, and never becomes sterile (15). Spoilage at this stage is known as "pinking" because of the characteristic pigment produced by the contaminating flora (19). Food poisoning was observed in association with spoiled and "pink" cod as early as 1886 (20), but the nature of the poisoning has not been clearly defined.

The fish is then hard dried by exposure to wind and sun and is no longer susceptible to such contamination unless stored in relative humidities of 75 percent and greater. Boury (21) has demonstrated, however, that *Staphylococcus pyogenes* var. *aureus* may survive in hard-dried cod fillets and even grow under suitable conditions of humidity.

This report has demonstrated the hazard of exposing salted cod to water at environmental

temperatures for extended periods of time. Although a preformed staphylococcal enterotoxin has not yet been demonstrated in salted cod during its processing or storage, the logical extension of available evidence forces one to consider this a strong possibility. More adequate information, therefore, is needed with regard to the safe hygienic standards in these phases for the protection of the public's health.

The study also illustrates the need for careful analysis of information obtained from field investigations of foodborne outbreaks, inasmuch as definite laboratory confirmation of causative factors often is not obtainable.

Summary and Conclusions

Two food poisoning outbreaks in Puerto Rico during the fall of 1957 were ostensibly caused by staphylococcal enterotoxin in salt-preserved codfish, a product that had not previously been incriminated in such mass intoxications.

The first outbreak, at the Ponce District Hospital, affected 303 persons and the second, 236 inmates of a juvenile delinquents' institution. Laboratory tests on samples of the codfish salad served in the second outbreak yielded strains of *Staphylococcus pyogenes* var. *aureus* when a 10 percent sodium chloride nutrient medium was used.

The findings support the view that partial preservation of codfish by salting does not completely destroy contaminating organisms which have a high salt tolerance. In fact, the addition of suitable concentrations of salt may serve to kill spoilage bacteria which might compete for growth with the staphylococcus.

These food poisoning experiences demonstrated the hazard of consuming salt-preserved codfish following its extended exposure to water at environmental temperature.

Enterotoxin production studies were carried out on cats in the laboratories of the Robert A. Taft Sanitary Engineering Center. When the animals received filtrates from cultures of strains isolated in the outbreaks, they did not give the response which typically follows injection of enterotoxin.

This type of test, however, results in non-specific responses. There is evidence, more-

pyogenes var. *aureus* in the codfish salad with an estimated concentration of 1.6×10^7 organisms per gram. All strains were confirmed by the Staphylococcal Unit of the Communicable Disease Center. The one isolated from the cod and two other coagulase-positive strains from rice and bread pudding proved resistant to the phage types used. Ten of the twelve food handlers were also shown to carry coagulase-positive *Staphylococcus pyogenes* var. *aureus* including six phage-resistant strains.

Enterotoxin Production

Isolated strains of staphylococci from the codfish salad served at the hospital and the institution for juvenile delinquents were referred to the Robert A. Taft Sanitary Engineering Center, Public Health Service, for enterotoxin production experiments.

Heated culture filtrates were tested by intravenous injection into cats. None of the laboratory animals receiving the filtrates prepared from the cultures gave the response which typically follows the injection of enterotoxin.

According to Dr. Foter, who supervised the enterotoxin testing at the Robert A. Taft Sanitary Engineering Center, there is at present no completely satisfactory experimental test for enterotoxin. The most reliable test is the feeding of suspected food to human volunteers, which is obviously impractical as a routine test.

The feeding of laboratory animals with suspected food results in nonspecific responses. In Dr. Foter's opinion, intravenous injection of a heated culture filtrate of staphylococci isolated from food into cats has limited value. The observations indicate that a positive response would be reliable, but the meaning of a negative response is not clearly understood.

Also, there is evidence that the laboratory animals used for this type of test, the monkey and the cat, are less susceptible to enterotoxin than man. An assay which can be performed quickly with simple equipment and with a high degree of reliability is urgently needed.

Discussion

The success of the medical school laboratory in isolating staphylococci from the codfish

salad was attributed to the use of milk with 10 percent sodium chloride agar for plating after making appropriate dilutions. This type of selective medium was not used by the food bacteriology section of the health department. *Staphylococcus pyogenes* has been shown to have a high salt tolerance (1), with enterotoxigenic strains proved capable of initiating growth in a 20 percent sodium chloride broth (2). Nutrient media containing 7.5 to 10 percent sodium chloride, in fact, have previously been demonstrated to be preferable for the isolation of *Staphylococcus pyogenes* from sources highly contaminated with other organisms (3,4).

To date there has been no demonstration that naturally occurring coagulase-negative *Staphylococcus pyogenes* produces enterotoxin (2,5,6), but the strain isolated in the outbreak at the Ponce District Hospital (from 4 different food samples by 2 laboratories) bears a suspicious relation to the etiology, and we believe it merits further study.

The time, temperature, and salt-concentration conditions that prevailed in the preparation of the salad prior to the Ponce hospital outbreak were duplicated in the food bacteriology laboratory. The extended desalting allowed luxuriant growth of staphylococci, but the seasoning and heating process before serving resulted in a marked diminution of these organisms. Therefore, a possibility to be considered is that an enterotoxin may have been produced by a strain of staphylococcus which was destroyed by final heating, and that the coagulase-negative strain appeared as a contaminant. It is unlikely that any of the temperature factors, detrimental as they may have been to these organisms, would have altered a formed toxin (7).

Phage typing of enterotoxin-producing strains of coagulase-positive staphylococci has received attention (8-10). Although it has been found that the great majority of the reported strains belonged to a reasonably easily defined group of phage patterns, approximately 12 percent were phage resistant, as was the case with the strain isolated from the codfish salad implicated in the outbreak at the juvenile delinquents' institution.

A brief review of the dry-salting process of

Serologic Evidence Of *L. australis* A In a Georgia Patient

L. E. STARR, D.V.M., Ph.D.,
M. M. GALTON, Sc.M.,
JOHN AMMONS, M.D.,
CHARLES LEMAISTRE, M.D., and
R. W. MENGES, D.V.M.

THE SEROTYPE *Leptospira australis* A Ballico was first isolated by Cotter and Sawers (1) in 1934 in northern Queensland, Australia. It was reported recently by Derrick and others (2) as the second most common serotype in Australia and accounted for 87 percent of the leptospirosis cases that occurred in cane-field workers. The principal animal carrier was found to be a native rat, *Rattus conatus* (3). In addition, this serotype was isolated from the kidney of a dog in Makasar by Mochtar (4) and from hedgehogs and yellow-throated mice, *Apodemus flavicollis*, in Czechoslovakia by Kmety (5).

No evidence of *L. australis* A infection was found in the United States until 1955, when two cultures isolated from raccoons in Decatur County, Ga. (6), were identified in the Communicable Disease Center's *Leptospira* Research Laboratory (7). Subsequently, presumptive identification has been made of 3 other isolations from raccoons and 1 from an opossum in southwestern Georgia.

In August 1956 a macroscopic slide aggluti-

nation test antigen was prepared from the first *L. australis* A strain isolated in southwestern Georgia. The antigen was incorporated into the battery of leptospiral antigens used to screen all human and animal serums examined in the laboratory. Routine use of this antigen led to the detection of *L. australis* A antibodies in serum from a patient in October 1957. The history of the patient's illness and the subsequent epidemiological investigation are described in this report.

Case History

J. W., a 14-year-old white schoolboy, awoke on October 11, 1957, with generalized malaise. Several hours later he had a headache accompanied by rapid onset of pain in both calves and knees that was aggravated by movement. The muscular pains spread to the thighs, and nausea with vomiting began. Fever was first noted in the evening of the day of onset. The following day, October 12, after 36 hours of clinical illness, he was admitted to Grady Memorial Hospital. On admission, temperature was 104° F. (rectal); pulse, 92; blood pressure, 130/65.

When questioned, the patient revealed that he had been swimming in a creek on a farm near Atlanta 10 days prior to admission. During the 2 weeks prior to onset of illness he had stayed with an aunt who owned a dog and several hogs. Many rats had been seen around the aunt's home and hogpens.

On examination, he appeared acutely ill and moderately lethargic. A generalized skin rash was present, most marked over the trunk, extremities, and face, but there was no eruption on either the palms or soles. Each circumscribed, maculopapular eruption measured 0.5 to 1.0 cm. in diameter and blanched on pressure. The pharynx was diffusely injected without exudate. There was no evidence of conjunctivitis, jaundice, joint tenderness, or swelling. Results of electrocardiogram were within normal limits. The initial white blood count was 8,300 per cc. with 76 percent segmented forms, 4 percent band forms, and 20 percent lymphocytes. The sedimentation rate was 41 mm. per hour. Urinalysis revealed a specific gravity of 1.025, 3 red blood cells per high-power field

Dr. Starr is public health veterinarian, division of epidemiology, Georgia Department of Public Health. Mrs. Galton is chief, and Dr. Menges, a veterinarian, Leptospira Research Laboratory, Epidemiology Branch of the Communicable Disease Center, Public Health Service, Chamblee, Ga. Dr. Ammons is assistant resident at Grady Memorial Hospital, and Dr. LeMaistre is associate professor of medicine, Emory University, both in Atlanta. This paper was presented at the meeting of the Southern Branch of the American Public Health Association on May 8, 1958, at Little Rock, Ark.

over, that both the monkey and the cat are less susceptible to enterotoxin than man. There is urgent need for a simple, fast, but reliable test for enterotoxin.

swamp rabbits, and 1 red fox were caught. *Leptospira ballum* was isolated from the kidney and urine of one opossum and its serum agglutinated with *L. ballum* antigen. No leptospirae were obtained from kidney and urine cultures of the other animals, and no leptospiral antibodies were detected. It is interesting that *Salmonella give* was isolated from the urine of another opossum and *Salmonella typhimurium* from the kidney of the third opossum.

It was learned that three other boys, ages 14 to 16 years, went swimming with the patient. When questioned, they stated they had not been ill. Serum samples were not obtained from them until approximately 3½ months after the patient's illness and no leptospiral antibodies were detected.

The aunt's dog had died shortly after the patient's illness. A local veterinarian stated that symptoms exhibited by the dog before death did not indicate leptospirosis.

Comment

The clinical symptoms exhibited by the patient and the demonstration of a rise and fall in antibody titer to *Leptospira australis* A. Ballico, together with a history of both direct and indirect exposure to animals, suggest a diagnosis of leptospirosis probably caused by a member of the *australis* A serogroup or a related serotype.

While the limited epidemiological studies did not reveal evidence of *L. australis* A infection in animals around the home in which the patient had stayed prior to his illness or in those that had access to the creek, *Leptospira ballum* was isolated from one of the opossums trapped near the creek. Previous studies in Virginia (8),

Louisiana (9), and Georgia (6) have shown that opossums may harbor at least seven leptospiral serotypes including *L. australis* A. Thus, the most likely hypothesis as to the possible source of the boy's infection appears to be the creek which may have been contaminated by infected opossums or other wild animals.

Air Pollution Control Association Meeting

The annual meeting of the Air Pollution Control Association will be held June 22-26, 1959, at the Hotel Statler, Los Angeles, Calif. The latest equipment for air pollution control will be displayed in the exhibit area, where experts will demonstrate the equipment and answer questions. Copies of papers presented at technical sessions will be incorporated in printed proceedings.

with only an occasional white blood cell. No albumin, sugar, or acetone was detected. Cerebrospinal fluid pressure, protein, and sugar content were within normal limits. There were 12 lymphocytes per high-power field.

Blood was obtained on the second full day of hospitalization (October 14) and cultured in Fletcher's medium for leptospires. The patient was then given injections of 600,000 units of procaine penicillin every 4 hours and of 250 mg. of chloramphenicol every 6 hours. Fever characterized the first 2 days after admission. Rectal temperature ranged up to 105° F. on the first day, but did not go above 100° F. on the second day, and thereafter remained normal. Marked subjective improvement occurred on the morning of the second hospital day. Although the total peripheral white blood count remained within normal limits, progressive lymphocytosis which reached 40 percent was present during the second week of hospitalization. Hepatic function was within normal range, and acute and convalescent serums were negative when tested for agglutination with typhoid, paratyphoid, brucella, and OX-19 antigens.

Skin biopsy of the rash showed a mild perivascular, acute inflammation. Muscle biopsy was unremarkable. The patient was discharged on the 10th hospital day and has remained well.

Serum obtained from the patient the third day after onset of illness was negative when tested by macroscopic slide agglutination with 12 leptospiral antigens, but a second sample collected on the seventh day of illness showed a positive slide test with *L. australis* A antigen. When tested by microscopic agglutination with a battery of 18 live leptospiral antigens, the second serum sample reacted only with *L. australis* A antigen to a titer of 1:200. For serum samples obtained from the patient on the 10th, 12th, 25th, and 42d days after onset of illness, titers of 1:1,600, 1:1,600, 1:400, and 1:400, respectively, were demonstrated against *L. australis* A antigen. (These titers were confirmed by A. D. Alexander, of the Walter Reed Army Institute of Research.) No reaction was obtained with the remaining 17 leptospiral antigens. Serum obtained from the patient 11 months later (September 1958) reacted to a titer of 1:100 with *L. australis* A antigen. No

leptospires were isolated from the blood cultured on the third day of illness.

Epidemiological Investigation

In early November, about a week after the patient was released from the hospital, a visit was made to his home to obtain further information regarding his possible exposure, but no one was at home. About a week later the patient and the aunt with whom he had stayed prior to his illness were found, and arrangements were made to visit the aunt's home and the site where the patient had been swimming. Conditions about the aunt's home were conducive to rat infestation. Although she had used warfarin about 3 weeks earlier, arrangements were made to set traps around the premises. Near the house were several hogpens with eight hogs standing in mud about 6 inches deep. Blood samples were collected from two of the hogs for leptospiral agglutination tests.

The creek where the patient had been swimming, approximately 4 miles from College Park, Ga., ran through a pasture in which cattle were grazing. The swimming "hole" was at the edge of a thickly wooded area. Fox and raccoon tracks were observed on the creek bank. Permission was granted by the owner to obtain blood specimens from the cattle and to set traps for wild animals in the vicinity of the creek. All trapping was done with the assistance and cooperation of the Fulton County Health Department, the U. S. Fish and Wildlife Service, and the Insect and Rodent Control Section of the Communicable Disease Center.

Twelve traps were set in and around the aunt's home and hogpens, but only one young rat (*Rattus norvegicus*) was caught, probably because of the recent use of warfarin. No leptospires were isolated from the kidney and urine of this rat, and no leptospiral antibodies were detected in the serum. Blood specimens from the two hogs were negative also in 12 leptospiral antigens when tested by slide agglutination.

Serum from 2 of the 4 cattle tested showed a weakly positive slide agglutination reaction to *Leptospira pomona* antigen. Traps were set in the vicinity of the creek for 3 nights, 15 to 20 traps each night. A total of 3 opossums, 3

"Whether we like it or not we live on a world scale; problems of sickness, ignorance, and hunger call for worldwide solutions. We can say where is the gate of a town; the frontier of a State, and what lines trace out the profile of a continent. But who could show on the map where the realm of tuberculosis begins or where the empire of illiteracy ends? Evils merge into one another. Just as the proximity of a sick person is a danger to the healthy, so the very existence of the ignorant and the starving is a disgrace to those who eat their fill and to those who enjoy the benefits of an education to which millions of their brethren have no access. And this disgrace is not without its dangers. . . . Progress cannot be other than collective if it is not to bear within it the seeds of its own destruction."—DR. JAIME TORRES BODET, *Secretary of Education of Mexico, quoted by Dr. Carlos Diaz-Coller.*

front of a drive toward eradication of malaria throughout the world. Eradication programs for smallpox, yaws, and urban yellow fever have also been approved by the governing bodies.

"Dr. Horwitz enjoys a distinguished career in public health. He brings to his new position a rich experience in the teaching and practice of public health in his own country, Chile, and in this organization. Dr. Horwitz has the advantage of some years of experience on the staff of the Pan American Sanitary Bureau and in recent years has served as his country's representative on the governing bodies of the organization. With his intimate knowledge of the organization's work, with the whole-hearted support of the member governments extended at the 15th Pan American Sanitary Conference and with the respect and affection which he enjoys among his colleagues on the Bureau's staff, the organization can look forward to a period of increasing fruitful activity under his leadership."—DR. FRED L. SOPER, *director emeritus of the Pan American Sanitary Bureau, Regional Office of the World Health Organization.*

The State of Well-Being

"The concept of health as stated in the opening words of the constitution of the World Health Organization—a state of physical, emotional, and social well-being—is a challenging one. It seems to me that this definition makes

'health' synonymous with 'happiness.' It is only natural that our efforts have been directed mostly toward the promotion of the physical well-being of people. All of us in the public health field recognize the present and continuing priority of the prevention of death and disease, so much of which is completely unnecessary in the light of present-day knowledge.

"I cannot let this occasion pass, however, without calling attention again to the wider concept of health. Obviously, physical well-being contributes to emotional and social well-being; nevertheless, I feel that those of us in the health field must also find methods to promote emotional and social well-being directly.

"To be successful, the malaria eradication programs of today require the active participation of local communities and individuals in local communities. It has been clearly demonstrated that to obtain this participation efficiently the techniques of the behavioral sciences must be used; thus knowledge in the emotional and social fields furthers physical health.

"Perhaps in the field of child health it is easier to illustrate a direct approach to emotional and social well-being. In the practice of pediatrics, in child health clinics and conferences, major emphasis has been on the child's nutrition and his protection against communicable diseases. The trend now, however, is for health workers to widen their scope and to consider the totality of the physical, emotional, and social well-being of the child. Disordered

New Chapter in Hemisphere Health

DR. Abraham Horwitz of Chile took the oath of office as director of the Pan American Sanitary Bureau, Washington, D.C., January 15, 1959, to begin his duties on February 1. A few days later, in Geneva, he was formally inducted as director, Regional Office for the Americas, World Health Organization. Dr. Fred L. Soper, who is completing his third 4-year term as bureau director, now becomes director emeritus.

Participating in the ceremonies held in the Hall of the Americas of the Pan American Union were Dr. Soper; Dr. Guillermo Arbona, secretary of health of the Commonwealth of Puerto Rico and president of the 15th Pan American Sanitary Conference; Dr. Jose A. Mora, Secretary General of the Organization of American States; and Dr. Carlos Diaz-Coller of Mexico, chairman of the executive committee of the Pan American Health Organization.

Selections from the remarks on this occasion follow:

The Pan American Health Organization

"The 1947 constitution of the Pan American Sanitary Organization, now the Pan American Health Organization, boldly declares its field to be the entire Western Hemisphere, and opens its doors to all governments of the Americas to participation in the coordinated effort to combat disease, lengthen life, and promote physical and mental health. The agreements negotiated with the World Health Organization in 1949 and with the Organization of American States in 1950 have set the pattern for bridging the gap between the United Nations system and that of the Organization of American States, with a single technical, nonpolitical operating agency representing both systems.

"The Pan American Sanitary Bureau was created in 1902 with the limited objective of aiding the American republics in preventing the spread of epidemic diseases from one maritime port to another with a minimal interruption to the movement of ships. [The Bureau serves as the operating arm of the Pan American Health Organization, which is a specialized agency of the Organization of American States, and also as regional office of the World Health Organization.]

"The inauguration of Dr. Horwitz finds the Pan American Health Organization with a declared long-range hemispherical program devoted to three general activities:

- The strengthening of the fundamental health services of all countries of the Americas.
- The expansion of education and training programs and facilities for health workers.
- The coordination of national communicable disease control programs in campaigns of total regional eradication.

"To these must be added a fourth which is becoming increasingly important: the development and administration of special cooperative, long-term combined research training and field demonstration control programs in special fields. The Bureau has pioneered in such programs in the fields of nutrition, yellow fever, aftosa (foot and mouth disease), and the zoonoses.

"The mere enumeration of these objectives emphasizes the need for, and the advantages of, a continentwide health program with full participation of all countries of the Americas. . . .

"The Pan American Health Organization has made far-reaching commitments. It is committed to the eradication of malaria from the Western Hemisphere. Here it is in the fore-

"Whether we like it or not we live on a world scale; problems of sickness, ignorance, and hunger call for worldwide solutions. We can say where is the gate of a town; the frontier of a State, and what lines trace out the profile of a continent. But who could show on the map where the realm of tuberculosis begins or where the empire of illiteracy ends? Evils merge into one another. Just as the proximity of a sick person is a danger to the healthy, so the very existence of the ignorant and the starving is a disgrace to those who eat their fill and to those who enjoy the benefits of an education to which millions of their brethren have no access. And this disgrace is not without its dangers. . . . Progress cannot be other than collective if it is not to bear within it the seeds of its own destruction."—DR. JAIME TORRES BODET, *Secretary of Education of Mexico, quoted by Dr. Carlos Diaz-Coller.*

front of a drive toward eradication of malaria throughout the world. Eradication programs for smallpox, yaws, and urban yellow fever have also been approved by the governing bodies.

"Dr. Horwitz enjoys a distinguished career in public health. He brings to his new position a rich experience in the teaching and practice of public health in his own country, Chile, and in this organization. Dr. Horwitz has the advantage of some years of experience on the staff of the Pan American Sanitary Bureau and in recent years has served as his country's representative on the governing bodies of the organization. With his intimate knowledge of the organization's work, with the whole-hearted support of the member governments extended at the 15th Pan American Sanitary Conference and with the respect and affection which he enjoys among his colleagues on the Bureau's staff, the organization can look forward to a period of increasing fruitful activity under his leadership."—DR. FRED L. SOPER, *director emeritus of the Pan American Sanitary Bureau, Regional Office of the World Health Organization.*

The State of Well-Being

"The concept of health as stated in the opening words of the constitution of the World Health Organization—a state of physical, emotional, and social well-being—is a challenging one. It seems to me that this definition makes

'health' synonymous with 'happiness.' It is only natural that our efforts have been directed mostly toward the promotion of the physical well-being of people. All of us in the public health field recognize the present and continuing priority of the prevention of death and disease, so much of which is completely unnecessary in the light of present-day knowledge.

"I cannot let this occasion pass, however, without calling attention again to the wider concept of health. Obviously, physical well-being contributes to emotional and social well-being; nevertheless, I feel that those of us in the health field must also find methods to promote emotional and social well-being directly.

"To be successful, the malaria eradication programs of today require the active participation of local communities and individuals in local communities. It has been clearly demonstrated that to obtain this participation efficiently the techniques of the behavioral sciences must be used; thus knowledge in the emotional and social fields furthers physical health.

"Perhaps in the field of child health it is easier to illustrate a direct approach to emotional and social well-being. In the practice of pediatrics, in child health clinics and conferences, major emphasis has been on the child's nutrition and his protection against communicable diseases. The trend now, however, is for health workers to widen their scope and to consider the totality of the physical, emotional, and social well-being of the child. Disordered

behavior is just as clear a sign of the failure of the health team as continued prevalence of malaria. We must eradicate malaria but we must also help the people, whose lives we save, to be happy and productive.

"I feel certain that as more knowledge is accumulated in the behavioral sciences we will be better able to understand the individual person as a physical, emotional, and social being, as a member of the family, and of the community. This knowledge will enable us health workers to make a much greater contribution to the happiness of the human being."—DR. GUILLERMO ARBONA, *secretary of health of the Commonwealth of Puerto Rico.*

The Purest Expression of Humanism

"After 57 years of effective accomplishment in the field of public health, the countries of this hemisphere have shown, without ostentation, the real possibilities of mutual understanding and cooperation for a noble cause. This is the essential meaning of the mission being performed by the Pan American Health Organization, of which the Pan American Sanitary Bureau is the secretariat. Its objectives are the purest expression of that humanism which thinks of man as the beginning and the end of all.

"To prevent disease, to prolong life, and to promote the health and welfare of the people are the purposes that our organization has been developing in this century, maintaining constant progress as our culture has evolved and as our society has gone through its vicissitudes. And for this reason, eradication of communicable diseases has been, and still is, in the forefront of the work of the organization.

"More than knowledge and experience, eradication of disease requires creative imagination, willingness to serve, perseverance, and courage. And these are some of the characteristics of the personality of Dr. Fred L. Soper, my illustrious predecessor, who has been called, with all justice, 'citizen of the Americas' in recognition of his work on behalf of continental health. . . .

"The path to be followed by the organization is well established. The doctrine is solid and clear, the principles and the methods well

proven, and the structure is flexible enough to be adapted to progress and needs. We will continue with the present programs of eradication of malaria and other scourges, and will start new ones against other diseases as soon as research and knowledge suggest the possibility. For eradication is a fight of man in his effort to survive against the designs of nature.

"While the countries are making substantial progress in this field, the need for more and well-prepared experts in the different branches of public health has become crucial. Their presence is indispensable for both national and international programs. Our organization will help to prepare them in the full breadth of the university spirit, having mankind and its environment as their ever-present objective. They should carry out their tasks mindful of the vision of the people and their feelings. With dedicated workers, every activity in public health is possible: to reduce infant mortality to rational levels, to provide better sanitation, to improve and to extend medical care, to strengthen local and national health services. In summary, to contribute to the welfare of the people and, thus, to the economic development of the countries.

"The technical progress of our time has increased enormously the scope and the consequences of human actions. It has stressed the need for a moral conscience above interests and conveniences. In the field of health our course is clear. The long and fruitful history of the Pan American Health Organization has demonstrated single-mindedness of purpose, looking steadily towards betterment of the health of the peoples of the Americas. Because I believe wholeheartedly that this goal is practical and realistic, I propose to continue the work of the organization along the lines which have been so well established. To achieve these ends I shall rely on the understanding and support of the member governments and their leaders in public health; on the joint effort of public and private international organizations, and on the devoted collaboration of the excellent staff of the Pan American Sanitary Bureau. I humbly offer my willingness to serve."—DR. ABRAHAM HORWITZ, *director of the Pan American Sanitary Bureau.*

Milk Sanitation Honor Roll for 1957-58

Seventy-one communities have been added to the Public Health Service milk sanitation "honor roll," and 41 communities on the previous list have been dropped. This revision covers the period from January 1, 1957, to December 31, 1958, and includes a total of 298 cities and 102 counties.

Communities on the honor roll have complied substantially with the various items of sanitation contained in the milk ordinance suggested by the U.S. Public Health Service. The State milk sanitation authorities concerned report this compliance to the Public Health Service. The rating of 90 percent or more, which is necessary for inclusion on the list, is computed from the weighted average of the percentages of compliance. Separate lists are compiled for communities in which all market milk sold is pasteurized, and for those in which both raw milk and pasteurized milk are sold.

The suggested milk ordinance, on which the milk sanitation ratings are based, is now in effect through

This compilation is from the Division of Sanitary Engineering Services, Bureau of State Services, Public Health Service. The previous listing, with a summary of rules under which a community is included, was published in Public Health Reports, September 1958, pp. 861-864. The rating method was described in Public Health Reports 53: 1386 (1938); reprint No. 1970.

voluntary adoption in 487 counties and 1,424 municipalities. The ordinance also serves as the basis for the regulations of 35 States and Hawaii. In 15 States and Hawaii it is in effect statewide.

The ratings do not represent a complete measure of safety, but they do indicate how closely a community's milk supply conforms with the standards for grade A milk as

stated in the suggested ordinance. High-grade pasteurized milk is safer than high-grade raw milk because of the added protection of pasteurization. The second list, therefore, shows the percentage of pasteurized milk sold in a community which also permits the sale of raw milk.

Although semiannual publication of the list is intended to encourage communities operating under the suggested ordinance to attain and maintain a high level of enforcement of its provisions, no comparison is intended with communities operating under other milk ordinances. Some communities might be deserving of inclusion, but they cannot be listed because no arrangements have been made for determination of their ratings by the State milk sanitation authority concerned. In other cases, the ratings which were submitted have lapsed because they are more than 2 years old. Still other communities, some of which may have high-grade milk supplies, have indicated no desire for rating or inclusion on this list.

Communities awarded milk sanitation ratings of 90 percent or more, 1957-58

publications

The Recognition of Lead Poisoning in the Child. *PHS Publication No. 620; 1958; 8 pages; 10 cents.*

A clinical description of lead poisoning in children is presented in this pamphlet written for the practicing physician. Emphasizing the imperative nature of early diagnosis, it discusses incidence, etiology, symptoms, laboratory confirmation, and treatment.

A short bibliography is included.

Vital Statistics of the United States, 1956. Volume I. *NOVS Publication; 378 pages; \$4.*

Similar in coverage to the 1955 report, this volume carries introductory material; all statistics for Alaska, Hawaii, Puerto Rico, and the Virgin Islands (U.S.); and marriage, divorce, natality, fetal mortality, and infant mortality statistics for the United States and each State.

The introduction, which includes 73 tables, discusses sources of vital data, history of vital registration, classification and interpretation of vital data, life tables, and analysis of the mortality statistics already published in volume II.

Recommended Dietary Allowances. *NAS-NRC Publication No. 598; 1958; 36 pages; \$1.*

On the basis of the best current scientific evidence, the Food and Nutrition Board recommends levels of nutrient intake considered most likely to provide maintenance of good nutrition for healthy persons in the United States. The allowances are obtainable from multiple combinations of dietary patterns.

Recommendations are made for calories, protein, calcium, iron, vitamin A, thiamine, riboflavin, niacin, ascorbic acid, and vitamin D. Also considered are other nutrients for which human requirements are not quantitatively established, but which

are likely to be included in the dietary patterns.

Copies may be purchased from the Publications Office, National Academy of Sciences-National Research Council, 2101 Constitution Avenue, N.W., Washington 25, D.C.

Tuberculosis Chart Series, 1958 Revision. *PHS Publication No. 639; 1958; 44 pages; 35 cents.*

A comprehensive presentation of the statistical aspects of tuberculosis in the United States, this revision combines some of the related topics in the 1957 edition and brings the material up to date.

Discussion of the usefulness of BCG and selected information from special studies are also included.

Organization and Staffing for Full-Time Local Health Services, December 31, 1956. *PHS Publication No. 634; 1958; by Clifford H. Greve and Josephine R. Campbell; 52 pages; 35 cents.*

The organization and staffing of 1,425 full-time local health units are analyzed.

Tables and charts show extent of coverage of the Nation by full-time local health organizations, selected characteristics of organized areas, financial capacity of those areas and their expenditures for public health, and public health personnel employed by official health agencies and by other official agencies.

The Industrial Environment: Its Evaluation and Control. Syllabus for short courses for industrial hygiene engineers and chemists presented at Occupational Health Field Headquarters, Cincinnati, Ohio. *PHS Publication No. 614; 1958; 36 pages; \$2.75.*

Lecture outlines, extensive reference lists, and laboratory exercises have been assembled to provide guidance to engineers and chemists new to the field of occupational

health and to furnish a review of basic procedures and techniques for experienced workers. The material has been developed in short courses presented by the Public Health Service.

The syllabus deals primarily with fundamental principles and methods used in the evaluation and control of the working environment, with emphasis on sampling and analysis and engineering control measures. Inplant air contaminants, radiation, noise, illumination, and ventilation are among the major topics. No material is included on clinical, toxicological, or physiological aspects of occupational health hazards.

Complimentary copies are restricted to students participating in the courses, but sale copies are available.

Sampling the Air. How air pollution is measured and studied. *PHS Publication No. 642; 1958; 5 pages; 5 cents.* Defines air pollution and describes its obvious effects. Sketches background and growth of national air sampling network. Outlines sampling procedures and resultant observations.

The Air We Live In. The health effects of air pollution. *PHS Publication No. 640; 1958; 7 pages; single copies, 10 cents, \$5 per 100.* Warns against polluted air. Describes effects as nuisance and health menace, recalls episodes of mass illness and fatalities, and discusses research.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared with Federal support.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Office of Information, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

NOTE: In these communities the pasteurized market milk shows a 90 percent or more compliance with the grade A pasteurized milk requirements, and the raw market milk shows a 90 percent or more compliance with the grade A raw

milk requirements, of the milk ordinance suggested by the United States Public Health Service.

Notice particularly the percentage of the milk pasteurized in the various communities listed. This per-

centage is an important factor to consider in estimating the safety of a city's milk supply. All milk should be pasteurized, whether commercially or at home, before it is consumed.

Geographic and Seasonal Variations in Births

BENJAMIN PASAMANICK, M.D., SIMON DINITZ, Ph.D.,
and HILDA KNOBLOCH, M.D.

IN previous investigations we have attempted to demonstrate the relationship of climatic variations during the first trimester of pregnancy to the birth of mentally deficient children. In the most recent study we tested the hypothesis that above-average summer temperatures during the third month of pregnancy, the critical period of fetal central nervous system development, are associated with an increased risk of being born mentally defective. This hypothesis was substantiated for the period of 1913-48 based on the date of birth, and therefore of conception, of mentally defective children admitted to the Columbus State School, Ohio (1).

We have shown also that complications of pregnancy are significantly more frequently encountered in pregnancies resulting in winter deliveries (2). The importance of this finding is that mental deficiency and neuropsychiatric disorders during childhood which are attributable to brain injury were highly associated with complications of pregnancy (3). Thus, the complications of pregnancy as well as mental deficiency were far greater among children conceived during the late spring and early

summer months than were expected. In interpreting this chain of evidence, we suggested that either decreased protein intake during the summer months or heat stress or both were etiologically related to the greater proportion of impaired children born during the winter months. Decreased protein intake and heat stress have been suggested as etiological factors in prenatal and postnatal mortality, morbidity, and congenital defects.

This study attempts to add still another dimension to our interest in climatic conditions and their impact on the birth process and prenatal and postnatal development. It has been known for a long time that there are marked seasonal variations in the birth rates in the United States and, indeed, throughout western civilization. According to data on all monthly births in 1955 by State, race, and sex which are reported in the United States vital statistics reports, there is a pronounced trough in the percentage of births occurring in the spring months of March, April, and May and a corresponding peak in the late summer months of August and September. This biannual variation applies to births of white and nonwhite and male and female children.

The August-September peak has traditionally and more or less facetiously been attributed to the longer and colder winter months. The explanation for the consistent spring dip in births has been more difficult to formulate. We believe that the annual spring decline in births may be attributed to three interrelated factors but primarily to the discomforts of high summer temperatures and high humidity. This

Dr. Pasamanick is director of research, Columbus Psychiatric Institute and Hospital, and professor of psychiatry, College of Medicine, Ohio State University. Dr. Dinitz is research associate at the institute and hospital, and assistant professor of sociology at the university. Dr. Knobloch is director, Clinic of Child Development, Children's Hospital, and associate professor of pediatrics and assistant professor of psychiatry at the College of Medicine.

ECHOES from Public Health Reports

An Experimental Study of the Relation of Hydrogen Ion Concentrations to the Formation of Floc in Alum Solutions.

By EMERY J. THERIAULT, Assistant Chemist, and W. MANSFIELD CLARK, Chief of Division of Chemistry, Hygienic Laboratory, United States Public Health Service

In approaching a scientific analysis of the art of water clarification it seems to us essential to distinguish the several aspects of the subject. These are so integrated in actual plant operation that it is difficult to perceive the true importance of each of the several factors which have to be mastered by the operator under every exigency. The isolation of phenomena, and their exact quantitative evaluation, will alone permit a true appraisal of any factor in relation to the process as a whole.

We have limited our attention to certain laboratory experiments which clarify one distinct aspect of the alum process. Our data doubtless lack the scope desirable for general practical application, but they indicate that, unless factors still to be investigated have an unexpected influence, maximum precipitation of added aluminium will occur within definite and narrow limits of hydrogen ion concentration.

It is well recognized that a precipitate is not formed from alum when the final solution is either too "acid" or too "alkaline." Hitherto the essential degree of "acidity" or "alkalinity" has been sought in the *quantity* of acid or alkali determined by one or another analytical method. More recently there has been a growing appreciation of the fact that the waterworks operator is dealing with reversible reactions, that his task is to control equilibria, and that all too many methods of the analyst, devised originally for the purpose of upsetting an established equilibrium to yield a definite value to the case at hand.

FEBRUARY 2, 1923, pp. 181-198

Emery J. Theriault collaborated with W. Mansfield Clark in showing the relation of hydrogen ion concentrations to the formation of floc in alum solutions, a basic contribution to further studies.

tures and long winters; (c) the three most northeasterly States (Maine, New Hampshire, and Vermont) characterized by cold winters and moderately cool summer temperatures; and (d) two northwestern States (Washington and Oregon) of temperate climate the year round.

The findings on the variations in the percentage of births by month and season of year in these four sets of States and in the United States tend to support the seasonal variation thesis with regard to births. Figures 1-5 present typical patterns in these regions. Our analysis is, however, based on all the aforementioned States. The southern States show a marked decline in births during the spring months and a correspondingly high peak in the number of late summer births. The midwestern and northeastern States show a lesser trough in spring births. The northwestern States of Washington and Oregon exhibit no spring trough at all. In fact, in these States the number of spring births is slightly higher than expected. The data also indicate, but not at all conclusively, that male births are fewer just prior to and during the descending curve of the spring depression. It has been demonstrated that males are apparently much more at risk of prenatal brain injuries than females (5).

Three interrelated factors are postulated as responsible for the decreased birth rate in the spring months in the United States as a whole and in the southern States in particular. First, it is suggested that uncomfortable temperatures in the summer reduce the frequency of coition and thereby the risk of conceiving during the summer months. This possibility was discussed previously. Second, an equally plausible hypothesis is that there is an increased fetal death rate among conceptions occurring immediately prior to and during the summer months. Some evidence is already available which lends credence to this proposition. For example, infant death rates in the first 28 days of life are higher in the spring months. Also, it has been shown that prenatal stress via the hypothalamic-pituitary-adrenocortical system and dietary deficiencies during the early critical period of fetal development, the first trimester, result in fetal deaths in animals (6).

The third explanation of the spring decline in births is purely statistical in character and admittedly accounts for a small fraction, at most 10 percent, of this decline. The argument here is that increased births during the peak summer months automatically decrease the risk of conception and delivery of children during the preceding and succeeding

Figure 4. Adjusted monthly variations in births of white males and white females in Maine, 1955.

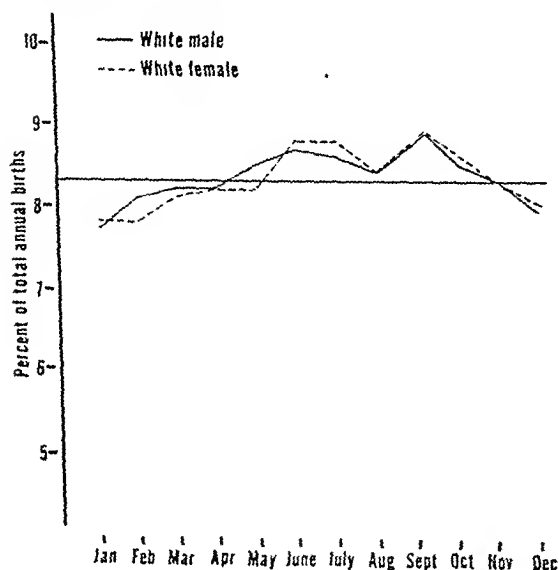

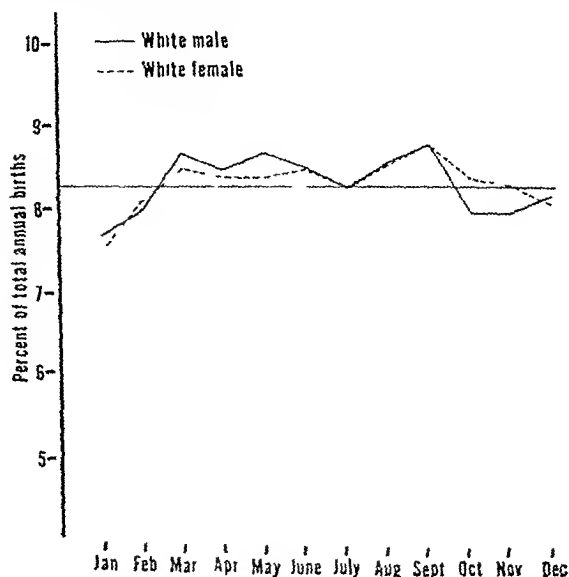

Figure 5. Adjusted monthly variations in births of white males and white females in Washington, 1955.

discomfort (there is now a single discomfort index combining temperature and humidity readings which is used by the U.S. Weather Bureau) probably reduces the frequency of coition and consequently of conceptions. It is also possible that high temperatures operate

Figure 1. Adjusted monthly variations in births of white males and white females in the United States, 1955.

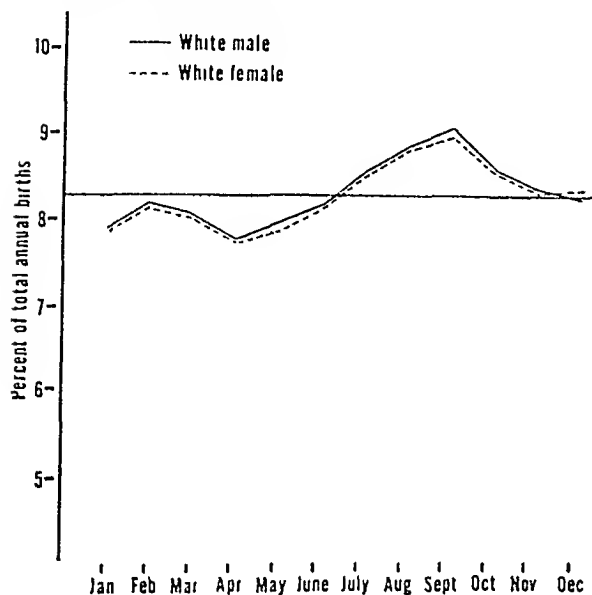

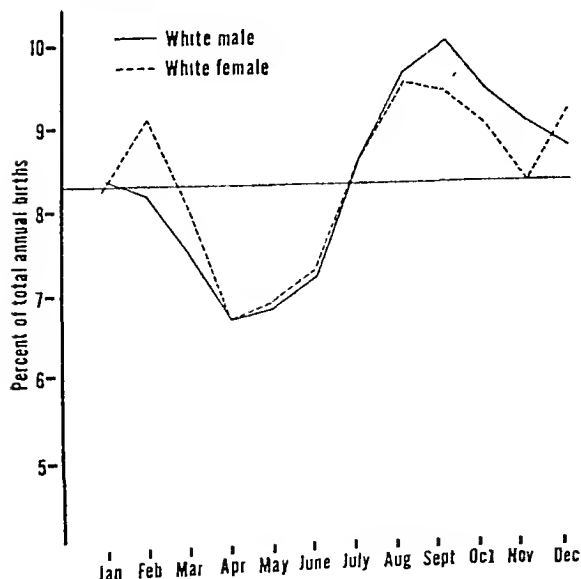

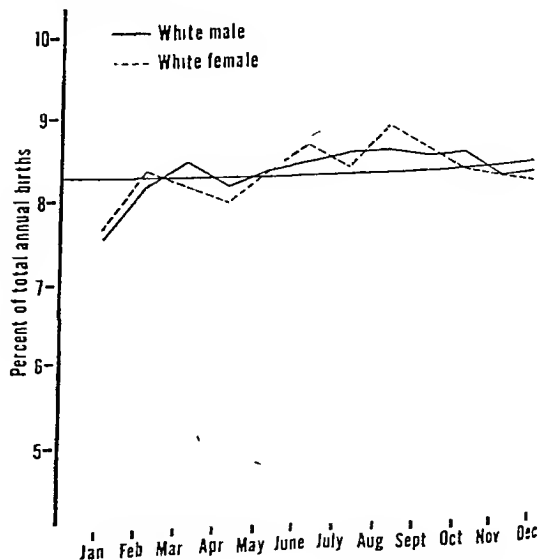

Figure 2. Adjusted monthly variations in births of white males and white females in Mississippi, 1955.

in some way (for example, sperm attrition) to reduce the conception rate when coition is held constant. Incidentally, if this hypothesis is correct, the spring trough in births should be significantly more characteristic of births among the lower socioeconomic status groups, who are less able to escape the summer temperatures, than among the higher socioeconomic groups. This hypothesis has already been substantiated in one major city, Baltimore, Md. Births among upper class families, according to our unpublished data, were significantly more random than among the lower socioeconomic groups or among nonwhites.

If it is true that the greater the discomfort index in the summer, the smaller the percentage of spring births, then States which have the hottest, most humid summers should have significantly lower spring births than States which have cooler, less humid summers. From the 1955 data on births by month of year, State, sex, and race (4), data for the following groups of States were selected: (a) three southern States (Alabama, Louisiana, and Mississippi) of relatively similar socioeconomic composition and with hot summers and relatively warm winters; (b) two midwestern States (Minnesota and Wisconsin) having relatively short summers with extreme tempera-

Figure 3. Adjusted monthly variations in births of white males and white females in Minnesota, 1955.

In this fifth-year study of children exposed to a fluoridated public water supply, it was found that the inhibition of caries is a function of the length of time they were exposed to fluoride prior to the eruption of their teeth.

Dental Caries in Maryland Children

After 5 Years of Fluoridation

A. L. RUSSELL, D.D.S., M.P.H., and CARL L. WHITE, A.B.

MARKED inhibition of dental caries after 5 years of fluoridation has been demonstrated in a series of independent studies of school children (1-8). This report describes a similar finding in somewhat more minute detail.

The children under study are residents of Prince Georges and Montgomery Counties, Md., immediately adjacent to the District of Columbia. All are white; all were born and have resided continuously in the area, and none has received such caries-preventive treatment as the topical application of fluoride solutions. Characteristics of the population, methods employed, and some of the techniques of analysis have been described in detail in previous publications (9, 10). In brief, teeth were examined under adequate light with mirror and explorer by a small and carefully calibrated group of examiners. "Catches" were not counted as carious lesions in the absence of other indications of caries. Examinations have been made yearly since 1952, when the community water was fluoridated. The fifth year results are presented in this paper.

In 1952 the Washington Suburban Sanitary Commission maintained two filtration plants,

which supplied the water used by the children in the study. The average daily fluoride content of finished water at one plant was 0.98 ppm during the first year and 0.94 ppm during the second; fluoride content of finished water at the other plant was 0.90 ppm during both years. From January 1954 to January 1957, the average daily determination was 1 ppm fluoride at both plants, with most monthly averages within the range of 0.97 to 1.03 ppm fluoride. Since July 1955, all water has been processed in a single plant. The fluoridating vehicle has been sodium fluosilicate.

Mean numbers of teeth in eruption were virtually the same in 1957 as in 1952. There were 1.2 percent fewer deciduous teeth present and 0.01 percent fewer permanent teeth present in 1957 than would have been expected on the basis of 1952 eruption data.

Total Caries Experience

Differences in total caries experience in the children between 1952 and 1957 are shown in tables 1, 2, and 3 and figures 1 and 2.

Significantly more children were free of caries in deciduous teeth at ages 5 and 6, and significantly more were free of caries in permanent teeth at all ages from 6 through 10, in 1957 than in 1952 (table 1). At 5 and 6 years of age, 87 percent and 49 percent, respectively,

Dr. Russell and Mr. White are with the National Institute of Dental Research, National Institutes of Health, Public Health Service, Bethesda, Md.

spring months. In some of the northern States with only a very minor annual spring decline this explanation alone might bring the curve up to the normal statistical expectancy.

A number of additional aspects deserve brief consideration in the interpretation of these findings. Major changes in marriage and birth patterns have occurred since the last war. Since we have restricted ourselves to postwar data, comparisons with earlier periods of time in the seasonal variations in these patterns should be a valuable next step in this series of studies. Nonetheless, it should be stressed that the impact of the seasonal peaks and troughs in marriages are biased against our hypothesis (that is, the effect of June marriages should increase the spring birth rate or at least help reduce the trough). Again, the improving economic situation of lower socioeconomic groups should, if our hypothesis is correct, eventually randomize the monthly variations in births in this stratum. Finally, the monthly birth variations for nonwhites are generally less extreme than for lower class whites. One plausible explanation for this phenomenon is the postulated greater stress encountered by nonwhites throughout the year so that stresses connected with high temperature add proportionately less variation in their birth rates than for lower class whites.

It would seem that the evidence, although in-

complete, suggests another application of preventive measures that may affect maternal and infant mortality and morbidity. The increased access of many persons in our society to the means of reducing the stress associated with semitropical summer climates might make a very real difference in infant and maternal mortality and morbidity.

Improper Drug Source Halted

Nasal inhalers containing basic amphetamine now will be sold only by prescription, as the result of a Food and Drug Administration regulation published in the *Federal Register* February 10, 1959. FDA received evidence of misuse of inhalers for nonmedical purposes by persons who removed the wicks and used the drug as a substitute for amphetamine tablets. The tablets always have been restricted to prescription sale but the inhalers have been sold directly to the public.

Action was taken on the basis of complaints of misuse from law enforcement officials and the agency's own investigation. Nasal inhalers containing other drugs are not affected by the ruling, the agency added.

¹ Decayed, missing, or filled.

² If 1952 rates had remained unchanged.

these incidence slopes in succession, it will be noted that the rate of caries increase is successively lower in each younger age group (see also table 3).

Mortality rates for permanent teeth were importantly lower in 1957 than in 1952, showing an overall decline at ages 6-13 of about 45 percent. But this change cannot be ascribed wholly to fluoridation, since a school dental health program was begun in the larger county shortly after the study began, and children examined in 1957 had, on the average, about one-third more filled teeth than were seen in children of the same ages in 1952. Filled teeth comprised 44.8 percent of the total number of DMF teeth in 1952 and 66.5 percent of the total number of DMF teeth in 1957.

Permanent First Molars

In the 2 years under consideration, most of the DMF teeth observed in children through 10 years of age were permanent first molars. Considerably fewer DMF first molars were found in 1957 than in 1952, with the differences generally related to the age of the children at the time of fluoridation. Table 4 shows the numbers of DMF permanent first molars which would have been counted in 1957 had the 1952 attack rates remained unchanged; these numbers are compared with the actual numbers seen in children aged 5-12 years.

¹ All children are native born and are continuous residents of the area; none has received topical fluoride or other caries-preventive treatment.

² Difference significant at the $P=.01$ level.

more children had caries-free deciduous teeth. Differences in permanent teeth ranged upward from 16 percent at the age of 6, with the greatest difference in 9-year-old children. At this age, nearly twice as many children with caries-free permanent teeth were observed in 1957 as in 1952.

Mean numbers of deciduous and permanent teeth with caries experience (the def and DMF means, respectively) are shown in table 2 for each age group in each of the study years. In 1957, fewer def teeth per child were found in children up through the age of 7 years and fewer DMF teeth per child in all age groups, than in 1952. Differences were significant in deciduous teeth for children 5 and 6 years of age and in permanent teeth for children aged 6-11 years. Data for the 2 years are compared in figure 1.

The incidence of new carious permanent teeth for each age-cohort over the period of observation is pictured in figure 2. Children who were 10 years old in 1952, for example, had an average of 3.09 DMF teeth; at the age of 15 years, 5 years later, the average had risen to 8.14, a mean increment of 1.01 new DMF teeth per child per year. For children 9 years of age and younger, the incidence is shown from a zero point at the age of 5 years, the time at which permanent teeth begin to erupt. If a straight edge is laid along each of

² If 1952 rates had remained unchanged.

these incidence slopes in succession, it will be noted that the rate of caries increase is successively lower in each younger age group (see also table 3).

Mortality rates for permanent teeth were importantly lower in 1957 than in 1952, showing an overall decline at ages 6-13 of about 45 percent. But this change cannot be ascribed wholly to fluoridation, since a school dental health program was begun in the larger county shortly after the study began, and children examined in 1957 had, on the average, about one-third more filled teeth than were seen in children of the same ages in 1952. Filled teeth comprised 44.8 percent of the total number of DMF teeth in 1952 and 66.5 percent of the total number of DMF teeth in 1957.

Permanent First Molars

In the 2 years under consideration, most of the DMF teeth observed in children through 10 years of age were permanent first molars. Considerably fewer DMF first molars were found in 1957 than in 1952, with the differences generally related to the age of the children at the time of fluoridation. Table 4 shows the numbers of DMF permanent first molars which would have been counted in 1957 had the 1952 attack rates remained unchanged; these numbers are compared with the actual numbers seen in children aged 5-12 years.

¹ If 1952 caries attack rates had remained unchanged.

² Difference significant at the $P=.01$ level.

In table 5, caries attack rates for permanent first molars computed from the 1952 data are compared with attack rates actually observed during this fifth year of fluoridation in those children aged 6-12 years who were examined in 1956 and reexamined in 1957. Though more caries-free first molars were present in children of each age group in 1957, these teeth were decaying at approximately the 1952 rates in children who were 4 years of age or older at the time of fluoridation. In children 3 years of age or younger at the time of fluoridation, attack rates were sharply and significantly lower than those seen in 1952.

In general, attack rates in mandibular first molars were more severe than attack rates in

maxillary first molars, but both tended to follow the same patterns with age.

Older Children

Children 12 years old or older have been slower to exhibit a caries-inhibitory effect following fluoridation than younger children, when comparisons are based on lifetime caries experience. The incidence of new DMF teeth in children aged 12 or 14 years at the end of the third year of fluoridation in these Maryland counties has been reported in an earlier paper (10). At the time of fluoridation those children were 10 or 11 years old. No decrease in the incidence of caries was evident in that group during the 1954-55 year.

¹ Decayed, missing, or filled.

² If rates observed in 1952 had remained unchanged.

³ Difference significant at the $P=.01$ level.

Similar data for the 653 children examined in 1956 and reexamined in 1957 who were 13 or 14 years of age at the end of the fifth year of fluoridation are shown in table 6. The differences between expected and actual numbers of teeth in eruption, in this group, were negligible; means of 26.33 and 27.38 teeth would have been expected on the basis of 1952 eruption data, and means of 26.24 and 27.35 teeth were actually observed. In 1957 there were slightly but significantly more DMF permanent first molars than had been seen in 1952. Means for the relatively caries-immune mandibular incisors and cuspids were essentially the same. Means for all other tooth types were significantly lower.

Crude incidence data may be computed from table 6. However, because of the greater numbers of teeth at risk, comparison with 1952 findings is more valid when based on attack rates (table 7). In general, the differences between expected attack rates and those observed during

this fifth year of fluoride exposure are related to the age of the tooth at the time of fluoridation. Permanent first molars, for example, had been in eruption about 3 years when first exposed to fluoride; the few remaining caries-free first molars were actually becoming carious at a faster rate than would have been predicted from 1952 findings. At the other end of the scale, permanent second molars, which erupted 2 to 3 years after fluoridation began, included significantly fewer carious teeth at the beginning of the year (see table 6), and attack rates during the year were sharply and significantly lower than expected. Attack rates were lower in all teeth erupting after fluoridation, but in only one of the teeth (the maxillary lateral incisor, with the shortest time at risk at that point) which were in eruption before fluoridation began.

Differences between expected and observed caries attack rates (omitting the mandibular incisors, teeth with attack rates too low for va-

lidity in a sample of this size) are shown in figure 3. In preparing this illustration teeth have been numbered from the midline toward the posterior part of the mouth. A bracket open at the top indicates position in the upper jaw, and a bracket open at the bottom indicates position in the lower jaw. The numeral 3 in a bracket open at the bottom, for example, indicates the mandibular cuspid.

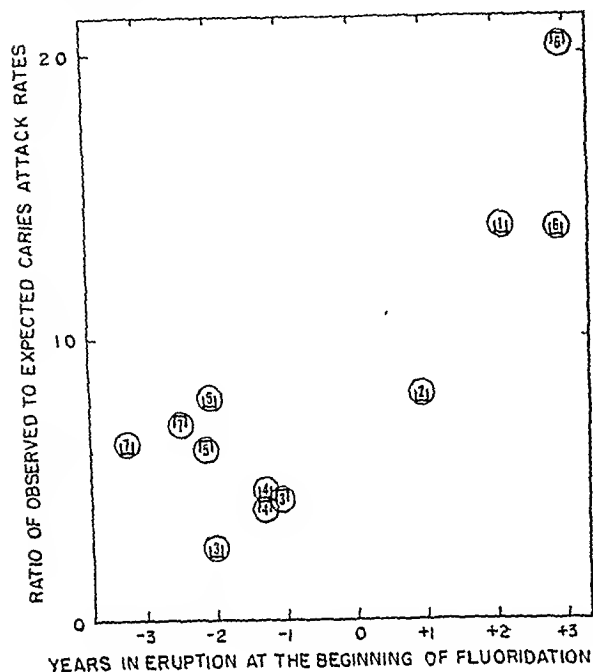

Discussion

So far as the deciduous dentition is concerned, little caries-inhibitory effect is evident in the data for children who were 2 years old or older at the time of fluoridation (7 years old or older in 1957). The most striking difference is shown in children aged 5 years in 1957, whose first waterborne fluoride exposure occurred during the period of calcification, and hence prior to

eruption, of these teeth. Six-year-old children showed an intermediate degree of inhibition. Their deciduous teeth were fully calcified, but not in eruption, at the time fluoridation began.

Similarly, the younger the child at the time of fluoridation the greater the degree of caries inhibition in permanent first molars. In older children the greater degree of caries inhibition was seen in those tooth types first exposed to fluoride at the earlier stages in development. The critical point would seem to be the time of eruption. Tooth types with first fluoride exposure essentially coincident with eruption show minimal caries inhibition, and those in eruption 2 to 3 years at the time of fluoridation show no inhibitory effect which can be detected in counts of DMF teeth. In short, at this point (the fifth year of fluoridation) and measured in this way, the degree of caries inhibition in any tooth type seems to be a simple function

Figure 3. Differences between expected caries attack rates and rates observed during the fifth year of fluoridation, by eruption status of teeth, Montgomery and Prince Georges Counties, Md.

of the length of fluoride exposure prior to eruption and the consequent risk of attack by dental caries.

Attack rates for children 13 or 14 years of age were slightly higher than expected during the third year of study (10), and they continued to be higher in permanent first molars in children of these ages in this fifth year. These facts suggest that (a) the prevalence of caries in this area may have been following an upward trend at the time the study was initiated, or (b) there may have been a gradual shift toward more stringent criteria over the course of the six yearly examinations.

Some such shift is inherent in the increased numbers of filled teeth. Bitewing X-ray examination is standard procedure in private dental offices in the area, which means that a proportion of these fillings represented lesions which could not have been detected by mirror and explorer until the following year.

In either event, the effect of such a shift would be toward a slight underestimation of the true magnitude of caries reduction.

Summary and Conclusion

A group of white, native-born children in Prince Georges and Montgomery Counties, Md., has been examined yearly since fluoridation of the community water supply in 1952. Their total caries experience after 5 years of fluoridation and the incidence of caries during the fifth year are compared with data from the baseline examination.

In this group at this time caries inhibition seems to be a simple function of the length of fluoride exposure prior to eruption of teeth and the risk of caries attack.

Simplified Method of Setting Clinic Fees

ALLEN HODGES, Ph.D.
DALE C. CAMERON, M.D.

IN its community mental health program, Minnesota is using the Federal income tax paid the previous year as the base for establishing the maximum fee for clinic psychiatric service. This method eliminates time-consuming investigations and complicated mathematical calculations. Yet it provides fee schedules tied to the patient's ability to pay, as required by State law. (Community Mental Health Services Act, 1957.)

The Federal income tax a patient pays is a fairly reliable index of his real economic situation, since it takes into account, in addition to income, such factors as number of dependents, other taxes paid, interest, and excessive medical and dental expenses. Still another advantage of using this figure is its ready availability, for almost everyone keeps a copy of his Federal income tax forms from year to year.

Currently, the maximum charge per clinic visit per family in the Minnesota community mental program is 1 percent of the Federal in-

come tax. (A family rate is provided when more than one member is attending the clinic, based on 1 percent of the Federal tax divided by the number of family members receiving service.) This percentage was set by the department of welfare, in consultation with private psychiatrists and lay groups concerned with mental health, to give what are believed to be realistic fees for service in this program. The percentage may easily be manipulated to alter the charges or to keep the charges the same should the base be altered (a change in the Federal tax rate, for instance). Examples of the fees that would be charged according to the 1 percent formula are given in the table.

In addition to the maximum percentage, a \$10 fee was set as the absolute maximum that could be charged. Prospective patients able to pay more than \$10 according to their income tax payments should be referred to private psychiatric services.

No charge, or only a token charge, is made if the individual paid no tax. Local mental health centers are free to make allowances for recent changes in income or other extenuating circumstances in setting fees within the statewide maximums.

Choice of these procedures for establishing fee schedules followed a survey of methods used in 92 outpatient clinics in Illinois, Minnesota, and New York and in the clinics of California's

Dr. Hodges, now assistant professor of educational psychology, University of Minnesota College of Education, Minneapolis, was until January 1959, the psychological consultant for the community mental health services program, Minnesota Department of Public Welfare, St. Paul. Dr. Cameron is director of the welfare department's division of medical services.

community mental health program. In all the grant-in-aid clinics, provisions are made for the care of psychiatrically indigent patients. Among patients making some payment the median minimum fee was 25 cents, for persons with annual incomes of less than \$2,000. The median maximum fee was \$15, for patients with annual incomes of more than \$7,000.

According to the survey, the fees charged are very similar from clinic to clinic and State to State, but the method of arriving at the annual income figures upon which the fee is based varies tremendously. Some clinics use a gross income figure, and others use an adjusted annual income figure calculated by complicated procedures which require considerable time.

Examples of maximum fees for psychiatric clinic visits

Minnesota community mental health program

	Gross income	Taxable income ¹	Taxes paid	Maximum fee per visit
<i>Single person</i>	\$4,500	\$3,450	\$719	\$7.19
<i>with no dependents</i>	5,000	3,900	818	8.18

A Diet Record Technique

MARY HELEN R. GOODLOE, B.S., CARROLL B. QUINLAN, M.D.,
and J. GORDON BARROW, M.D.

A DIET record technique adapted by us for use in a study of the dietary habits of Trappist and Benedictine monks is described in this report. The study was undertaken to determine whether the dietary habits of the two monastic populations differed sufficiently, especially as regards fat intake, to make them suitable for investigating the relationship between the development of atherosclerosis and dietary habits. No detailed analysis of the diets is given in this paper.

Participation in the study was on a completely voluntary basis. Sixty-five Benedictines (93 percent of the community) and 82 Trappists (97 percent of the community) participated in the study.

The Trappist community abstains from eating meat and consumes a lacto-ovo-vegetarian diet. Previous studies (1,2) of the Trappist diet suggested that it was much lower in fat content than the one consumed by most Americans. The Benedictine community, on the other hand, is omnivorous, consuming a diet which in outward appearance is typically American.

Both monasteries are cloistered and their regulations prohibit women from entering the community. Since we did not have a male nutritionist to conduct individual dietary interviews, the dietary history technique described by Burke (3) was not feasible. The size of the

communities, the long-term aspect of the study, and the lack of personnel and of laboratory facilities precluded the use of detailed balance studies involving measured food intake and fecal and urinary output. These unique circumstances required that a suitable technique be devised for obtaining reliable and valid individual diet characterizations. The repetitive diet record technique (4) described below was felt to be the most suitable for our purpose.

The two religious communities have many things in common regarding the preparation and serving of food. However, there were certain differences which required that the dietary record technique be modified slightly in each monastery.

The Qualitative Aspect

In both the Trappist and Benedictine monasteries the monks eat in a common refectory, and the food is prepared in a central kitchen. There is no selective menu in the sense of a choice of foods. Their only choice is whether or not they eat what is served and in the quantity of each item consumed.

The information obtained from the monastery cook in the central kitchen during the study is termed by us the "qualitative aspect" of the diet record. The method of deriving this qualitative information was as follows in both monasteries. On the day selected for dietary study the physician (Quinlan), acting as liaison between the monastery and the research nutritionist (Goodloe), obtained from the monastery cook the following information:

1. The recipes for each food prepared, including brand and trade names of the ingredients used.

The authors are associated with the Heart Disease Control Program of the Georgia Department of Public Health, Atlanta. Mrs. Goodloe is research nutritionist, Dr. Quinlan, associate director, and Dr. Barrow, director of the program. Their research was supported by Grant No. H-3262 from the National Heart Institute, National Institutes of Health, Public Health Service.

2. The total amount of each food prepared and served to the community.
3. The number of monks who ate the meal.
4. The amount of each food which was returned to the kitchen as waste.
5. In the case of individual food servings, the weight, size, or number of items in a serving (for example, the weight of one pork chop, the number of peach halves in a dessert serving, the weight of a slice of bread, and so on).

The Quantitative Aspect

Although both monasteries prepared their food similarly in a central kitchen, the method of serving the food differed in the Trappist and Benedictine communities.

In the Trappist monastery the main food items were served from a common table. Each monk received an equal amount of each food and drink. Thus each monk received one serving of potato, one bowl of soup, one tin of coffee, one dessert, and so on. The Trappists were not allowed second helpings of these basic foods. There were, however, a few items, such as bread, sugar, and peanut butter, which could be taken as desired.

The food in the Benedictine monastery was served in a different manner. The food prepared in the central kitchen was placed on the common refectory table, and each monk took as much or as little of each food as he desired.

Many of the foods had been divided in the kitchen into individual servings (for example, one baked pork chop, a brick of ice cream, and so on), although there were a few foods, such as mashed potatoes and string beans, which were served in bulk form.

The information obtained from each monk during this study has been termed the "quantitative aspect" of the diet record. This quantitative information was obtained in both monasteries from diet records kept by the monks. On the day selected for dietary study each monk was given a mimeographed menu listing all the food items which were being served on that particular day. Each monk took this menu with him to the refectory and noted during the meals the number of servings of each item which he consumed. Additional space was allotted on the diet questionnaire to indicate foods which were provided on special diets or eaten between regular meals.

Standardization of Food Servings

Since each monk reported bulk items in his quantitative diet record in terms of the number of servings consumed, it was necessary to standardize the amount represented by "a serving."

This standardization of servings was not difficult in the Trappist monastery since each Trappist monk was served the same amount of food from a common table. A sample meal was

Method used in a dietary record technique for deriving average caloric intake per person per day in a Trappist monastery

Type of day	Calories per diet	Average value for each type of day	Frequency of each type of day during year ¹	Total yearly value for each type of day (in calories)
Fast day:				
Diet No. 1	2,383	2,375	103	244,625
Diet No. 3	2,367			
Feast day:				
Diet No. 4	4,421	4,421	60	265,260
Regular day:				
Diet No. 2	3,350	3,394	202	685,588
Diet No. 5	3,508			
Diet No. 6	3,324			
Total				1,195,473
Daily average (total ÷ 365)				3,275

¹ Represents the method of weighting the caloric intake for each type of day.

brought from the Trappist monastery to the research nutritionist who measured the amount of each serving by weight and volume. Items such as sugar and peanut butter, which were available in any quantity desired, were reported according to the number of spoonfuls consumed, using a standard soup spoon which we supplied the monastery. The capacity of all ladles, scoops, drinking mugs, and soup bowls used in serving the food was carefully measured.

The standardization of food servings at the Benedictine monastery was difficult only for those items which were not prepared as individual servings but were presented in bulk form. In order to standardize these servings, standard food models were demonstrated at the monastery showing the monks several examples of what we considered one standard serving. They were requested to keep this idea of a serving in mind when they filled in the quantitative diet record.

Reproducibility and Accuracy

A review of repetitive diet records shows that individual monks regularly eat the same amount of certain foods such as bread, sugar, and coffee. This fact strengthens the argument for the reliability of this diet record technique (5).

In order to check the accuracy with which the participants filled in the quantitative diet record sheet, the amount of a given food item reported by all the monks was totaled (for example, the total number of servings of mashed potato reported consumed by the whole community). This figure was compared with the total quantity of this food item which the cook reported he had prepared minus the waste which was returned to the kitchen. It was found that these two figures agreed closely when checked many times with different foods.

It is interesting that the results obtained for the Benedictine monks, whom we considered to be consuming an average American diet, checked closely with dietary studies (6,7) of other populations elsewhere in this country as regards total calories and percentage of calories from fat, protein, and carbohydrate.

Technique of Dietary Computation

The recipes obtained from the monastery cooks were analyzed, and the calories and nu-

trients in a serving of each food were calculated by using standard food tables (8-11). In addition, two food items in common usage were analyzed by the Georgia Department of Agriculture. The wheat grown by the Trappists and used in making bread, which is a staple item in their diet, was analyzed for fat and protein content (fat, 1.4 percent; protein, 13.0 percent). The milk in use at each monastery was analyzed for fat content (Trappist, 5 percent; Benedictine, 5.4 percent).

This information was combined with the quantitative aspect of the diet record filled out by each monk, and a complete dietary analysis for each individual was computed for that day in terms of the following dietary components (9):

Calories	Vitamin A, IU
Animal protein, gm.	Thiamine, mg.
Vegetable protein, gm.	Riboflavin, mg.
Animal fat, gm.	Vitamin C, mg.
Vegetable fat, gm.	Saturated fatty acids, gm.
Cholesterol, mg.	Unsaturated fatty acids, gm.:
Carbohydrate, gm.	linoleic acid, gm.;
Calcium, gm.	linolenic acid, gm.;
Phosphorus, gm.	arachidonic acid, gm.
Iron, mg.	

Selection of Days for Study

The diet in both monasteries is affected by seasonal variation and religious tradition (1,2). The winter and summer diets differ, and these in turn may be subdivided into fast days, feast days, and regular days. The study days in each community were selected arbitrarily with the provision that both summer and winter, and fast, feast, and regular days were represented. Care was taken to space the study days throughout the year. Weekends, periods of fast (such as Fridays and Lent), and special feast days were equally represented in the diet study days chosen in each community.

On several occasions the monastery cook was requested to keep a 10-day record of the foods which were served in the monastery. These 10-day surveys were reviewed to make sure that the study days differed in no way from the menus which were being served in the monastery on days which were not being studied.

In calculating the average diet for the year for each monk the results of the individual daily

diets studied were weighted in proportion to the frequency with which that type of diet appeared during the year. For instance, six diets were studied for each individual in the Trappist monastery; one feast day, two fast days, and three regular days were represented. The weighting of each diet in obtaining the average diet for the year was accomplished as follows.

There were 202 regular days in the year. The nutrients on three of these days were averaged and multiplied by 202. These total values for regular days were added to the total values for the same nutrients on feast days and fast days weighted in the same fashion, and the yearly total was obtained. Dividing any one of these totals by 365 yielded the average daily consumption of this particular nutrient by this individual monk (see table).

Preliminary Results

A wide variation in dietary habits between monks within each group has been observed, and this has led us to believe that any epidemiological study of the relationship between diet and atherosclerosis must take into consideration the average individual dietary intake and not the average food habits of that particular group. Therefore, on planning further study of these two groups it is felt that continued individual diet analysis will be necessary.

Repetitive diet records were obtained for 82 Trappist monks and 65 Benedictine monks. Six diets were calculated for each Trappist and 4 for each Benedictine. Preliminary results were:

Calories	Benedictine	Trappist
Average per day-----	2,896	3,203
Fat (percent)-----	45	26
Protein (percent)-----	13	10
Carbohydrate (percent)-----	42	64

Statistical analysis in relation to fat content of the respective diets has shown that the two groups differ significantly in their percentage of calories derived from fat (t test: $P < 0.001$).

Summary

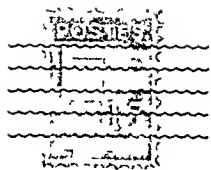

In a repetitive dietary record technique adapted for use in a study of Trappist and

Benedictine monks, quantitative and qualitative dietary records were used in calculating average daily individual dietary intake. Results indicate that the method is a substantially reliable and accurate one.

Preliminary findings show a significant difference in the fat content of the diet of the two communities. It is concluded that the two groups are suitable for the study of the relationship between dietary habits and atherosclerosis.

INTERNATIONAL MAIL POUCH

Yaws in Gwagwalada

A request by medical authorities at Kaduna, capital of the Northern Region of Nigeria, for a survey of prevalence of yaws brought me to the small territory of Abuja where, shortly after 6 a. m., I met the local emir. He asked me, as a personal favor, to examine and treat the members of his household. At his harem, I examined his four wives, relatives, servants, and a great number of children; my nurse gave each the prescribed injection of penicillin.

An hour later, we packed our equipment into the Land Rover, and, followed by the emir in his car, drove 75 kilometers to Gwagwalada. Several hundred people were waiting, sitting quietly on the ground in the village square. They had come from 15 or 20 different villages. Some had walked 10 to 15 kilometers that morning. I set up my table in the square, with the emir on my left and on my right a nurse who noted the results of the examinations on a separate record for each patient.

It is not strictly necessary to give treatment when making a survey of this kind. But these people had come so far and so seldom see a doctor that we had agreed, although it meant extra work, that each man, woman, and child should get an injection of penicillin. It would cure yaws and many other ailments, such as ulcers, infected sores, pneumonia, and gonorrhea.

One patient followed another in a steady stream. After being examined and registered, they went to the treatment hut where a male nurse scrubbed each right buttock with soap and water and an assistant dried and swabbed it with alcohol. The patients then placed both hands on a waist-high horizontal bar while a specially trained nurse gave the intramuscular injection of the dose prescribed. The villagers laughed and joked as they passed along the line.

As I worked I noticed that the farther the villages were from the road, the more their people suffered from yaws. Gwagwalada had only 1 percent of infectious cases and 4 percent of yaws of all types; villages 10 to 15 kilometers away showed rates of 7 percent and 13 percent.

At 4 p. m. new groups of men and women, carrying their children, began to arrive. They came from an almost inaccessible village, reached only by fording 2 or 3 big rivers. They had not been told to come, but, hearing about a doctor who was giving away a marvelous remedy which would cure many ills, they had set out forthwith on their long, hard trek. One of them, an old man carrying a child of 5 or 6 years, told me it was the first time anything like this had happened to his people.

The day's work ended at 6 p. m., and we were very tired. *Since early morning we had seen and treated 2,125 persons.* Our supply of penicillin was finished, and the treatment hut looked like a battlefield.

—DR. JEAN FRAISEE, *medical director of the anti-yaws campaign in Nigeria, summarized from his report published in World Health, September-October 1958.*

Rehabilitation Bookshelf

The International Society for the Welfare of Cripples and the Committee for the Handicapped of the People to People Program has given a 43-volume rehabilitation bookshelf to the Faculty of Medicine, Istanbul University. It is the first such gift to a library in another nation.

In behalf of the society and the committee, William C. Gorthy, director of the Institute for the Crippled and Disabled in New York City, presented two token volumes to Dr. Uveys Maskar, acting dean of the faculty in Istanbul, on November 20, 1958.

The token volumes, tooled, stamped, and hand-bound in fine leather by handicapped clients receiving training in the institute's vocational rehabilitation service, were Rehabilitation Center Planning, published by the Department of Health, Education, and Welfare, and Rehabilitation, A Community Challenge, by W. Scott Allan.

Correction: The editors regret the error that linked the campaign against rats in Korea, reported in February, to the typhoid fever program. The error was not the author's.

Community Responsibility for Mental Health

JOHN D. PORTERFIELD, M.D.

THE OTHER night, as bedtime literature, I resumed reading in the Evans' Dictionary of Contemporary American Usage and ran across this bit of historiography stimulated by the words "incubus" and "succubus."

"In former times," they write, "when demonology was a more exact science, an *incubus* was a male demon which haunted the sleep of women and was responsible for their bearing witches, demons, and deformed children. The innocent maiden, however, plagued by his advances could protect herself with St. Johnswort and vervain and dill. The *succubus* was the female counterpart. The offspring of the union of a man and a succubus was demonic, but the proper prayers, spells, or charms recited by the man upon awakening would prevent its conception. These distinctions no longer hold in standard common usage, but the learned preserve them and delight in them."

After twinkling briefly over the sly dig at the learned class to which the Evanses inescapably belong, I made a mental note to inquire on the following day whether St. Johnswort, vervain, or dill had any medical properties either separately or in combination, and gave a less specific instruction to my subconscious to check on modern analogues of spells and charms.

I would consider with you for a few moments this question of spells and charms and the modern counterparts in what we now call mental health.

It should be understood that I am not a psy-

chiatrist. My professional career has been devoted almost exclusively to public health administration. In my view this general term includes everything related to the establishment of communitywide health programs, of which, of course, mental health is an important component. In my pursuit of this specialty I have had a number of occasions to observe closely all of the aspects of programs for the detection, diagnosis, treatment, and prevention of mental illness and for the promotion of good mental health. Fortunately, I have been one of that growing number of people who have assailed the problem of integration of mental health and community health from both sides.

In the course of accumulating this experience I have developed some strong feelings and a few firm opinions about this matter of community mental health. From the vantage point of this experience I would like to consider a serious problem which is ours as citizens of the modern American community.

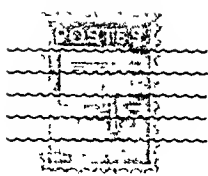

The Meaning of Mental Health

To discuss all of the bands in the spectrum of mental health would take too long. To be sure, the term "mental health" needs some definition.

We paradoxically include under this heading all the varied and difficult problems posed by mental illnesses and emotional disorders. We go quickly, sometimes too quickly, beyond this to a host of other problems perhaps because of the magnitude of the problems and the difficulties involved in attempting to develop measures to deal with them.

Beyond the frank psychoses and the psychoneuroses is a whole field of personality dis-

Dr. Porterfield is Deputy Surgeon General of the Public Health Service. This paper is based on a talk before the 27th General Assembly, Council of Jewish Federations and Welfare Funds, at the Shoreham Hotel, Washington, D. C., November 14, 1958.

Yaws in Gwagwalada

A request by medical authorities at Kaduna, capital of the Northern Region of Nigeria, for a survey of prevalence of yaws brought me to the small territory of Abuja where, shortly after 6 a. m., I met the local emir. He asked me, as a personal favor, to examine and treat the members of his household. At his harem, I examined his four wives, relatives, servants, and a great number of children; my nurse gave each the prescribed injection of penicillin.

An hour later, we packed our equipment into the Land Rover, and, followed by the emir in his car, drove 75 kilometers to Gwagwalada. Several hundred people were waiting, sitting quietly on the ground in the village square. They had come from 15 or 20 different villages. Some had walked 10 to 15 kilometers that morning. I set up my table in the square, with the emir on my left and on my right a nurse who noted the results of the examinations on a separate record for each patient.

It is not strictly necessary to give treatment when making a survey of this kind. But these people had come so far and so seldom see a doctor that we had agreed, although it meant extra work, that each man, woman, and child should get an injection of penicillin. It would cure yaws and many other ailments, such as ulcers, infected sores, pneumonia, and gonorrhea.

One patient followed another in a steady stream. After being examined and registered, they went to the treatment hut where a male nurse scrubbed each right buttock with soap and water and an assistant dried and swabbed it with alcohol. The patients then placed both hands on a waist-high horizontal bar while a specially trained nurse gave the intramuscular injection of the dose prescribed. The villagers laughed and joked as they passed along the line.

As I worked I noticed that the farther the villages were from the road, the more their people suffered from yaws. Gwagwalada had only 1 percent of infectious cases and 4 percent of yaws of all types; villages 10 to 15 kilometers away showed rates of 7 percent and 13 percent.

At 4 p. m. new groups of men and women, carrying their children, began to arrive. They came from an almost inaccessible village, reached only by fording 2 or 3 big rivers. They had not been told to come, but, hearing about a doctor who was giving away a marvelous remedy which would cure many ills, they had set out forthwith on their long, hard trek. Rehabilitation Bookshelf

The International Society for the Welfare of Cripples and the Committee for the Handicapped of the People to People Program has given a 43-volume rehabilitation bookshelf to the Faculty of Medicine, Istanbul University. It is the first such gift to a library in another nation.

In behalf of the society and the committee, William C. Gorthy, director of the Institute for the Crippled and Disabled in New York City, presented two token volumes to Dr. Uveys Maskar, acting dean of the faculty in Istanbul, on November 20, 1958.

The token volumes, tooled, stamped, and hand-bound in fine leather by handicapped clients receiving training in the institute's vocational rehabilitation service, were Rehabilitation Center Planning, published by the Department of Health, Education, and Welfare, and Rehabilitation, A Community Challenge, by W. Scott Allan.

Correction: The editors regret the error that linked the campaign against rats in Korea, reported in February, to the typhoid fever program. The error was not the author's.

huge institutions, overcrowded and understaffed as they are, tend to defeat the purpose for which they were established. Leaders in the field of psychiatry have suggested that mental hospitals hold from 200 to 500 patients only. But this requires many more trained professional workers, as well as new buildings.

The relatively new idea, in this country at least, of the "open" hospital, in which patients are helped to use their own resources for independent and responsible activity, requires more than merely throwing away the keys to the doors. Custodial care is relatively simple. In an open hospital, trained people are needed to plan and conduct active treatment. We need more personnel, too, to staff the "day" hospitals, where patients who live at home can get treatment during the day, and the "night" hospitals, where patients who hold full-time jobs return for treatment at night. For these groups, as well as for recently discharged patients, there should be more halfway houses, sheltered workshops, convalescent homes, foster home care, and help with legal and personal problems. Perhaps more than anything else, a sympathetic community is needed—a community that will accept the former patient as relative, friend, neighbor, and fellow employee, without prejudice or discrimination.

But what of the problem of mental illness outside the hospital? Surveys have estimated that about 6 percent of the population, or close to 10 million people, are seriously enough disturbed to need treatment. The percentage appears to be even higher in overcrowded, economically depressed areas in some of our larger cities. It has also been estimated that 50 percent of the patients seen by general practitioners for physical complaints are suffering from some form of mental disorder, and that their complaints are at least partially psychogenic.

The magnitude of the problem of maladjustment in children, as evidenced in school problems and in a demand for outpatient clinic services that far exceeds the supply, is well known today. So is the extent of juvenile delinquency and divorce and broken homes. In addition, some 3 percent of the population, or close to 5 million individuals, are mentally retarded.

In the face of this almost overwhelming array of problems, we find ourselves singularly handicapped in terms of resources. For one thing, we are desperately short of trained, professional personnel in mental health. Surveys in different parts of the country have shown that we need 3 to 5 times as many psychiatrists and psychiatric social workers as we now have, 4 to 7 times as many psychologists, and 5 to 7 times as many psychiatric nurses.

The number of outpatient psychiatric clinics has increased considerably during the past few years. But the total number, about 1,200, only half of which operate on a full-time basis, is far short of the need. Only a handful of residences are currently available for inpatient treatment of psychotic children. The result is that these children either lack treatment or are thrown together with adult mental patients.

Search and Research

Fortunately, we are beginning to see some progress. I have already mentioned some of the recent gains in care and treatment. A great deal has also been done to help meet the need for trained personnel. During the past decade, a considerable number of psychiatrists, clinical psychologists, psychiatric nurses, and psychiatric social workers have been trained with funds made available under the National Mental Health Act. The Public Health Service's National Institute of Mental Health also provides funds to include psychiatric training in the curriculums of medical schools and collegiate schools of nursing. Research fellowships and other grants have helped to train some of the people needed to do research in mental health.

Research into the cause, treatment, and prevention of mental diseases is a long, complicated, and expensive undertaking. Here, too, the Federal Government provides support and stimulus. Investigators in research centers throughout the country are conducting a wide range of biological, psychological, and sociologic studies with Federal aid. In addition, NIMH conducts mental health research in its own laboratories and clinical facilities.

Out of this work, new knowledge is emerging about the structure and functioning of the

orders which manifest themselves in problem behavior, such as drug addiction, chronic alcoholism, delinquency, and psychosomatic illness. Mental retardation and its effects on family and community are also the concern of mental health. Over and above these, however, is a broad range of problems which have become rather loosely incorporated under the term "mental health."

This range encompasses an almost bewildering array of failures in living. Examples can be drawn from practically every area of human activity and from every one of the "ages and stages" of man's growth and development. I need not spell them out. The problems of marital adjustment and divorce, of parent-child frictions and maladjustment to school, of absenteeism and failure in work, of the older person seeking a satisfactory way of life, the generalized unhappiness of individuals and families, the failures of people to cope with the world—whether because they are too weak or the stress of circumstances too great—all of these and more are the daily problems dealt with by both health and social agencies.

Increasing emphasis on prevention has further broadened the field of mental health. Many agencies have become concerned with what is termed building "positive mental health." This is an area of much complexity and more than a little ambiguity.

Some attempt at definition was made by Dr. Marie Jahoda in a monograph, *Current Concepts of Positive Mental Health*, the first in a series of publications by the Joint Commission on Mental Illness and Health, authorized by the Congress to conduct a survey of the national mental health problem. Dr. Jahoda starts with the assumption that absence of illness and presence of health overlap, but do not necessarily coincide. She analyzes the psychological content of the various criteria that have been suggested as indicators of positive mental health. Included are attitudes of the individual toward his own self, his sense of identity, the style and degree of his growth and development, the ways in which he uses his psychological resources, his autonomy, his perception of reality, and control of his environment.

All of these concepts, together with the ques-

tion of how social adjustment can be made to coincide with individual independence and integrity, are familiar. These are the factors which all of us consider in planning a coordinated community approach to social needs.

The New Look in Care

As a physician and an administrator, however, I tend to proceed on the basis of practicality. My operational principle is that the promotion of health is tied to those preventive measures which reduce the likelihood of disease. As practical workers in community welfare services, we are vitally concerned with the prevention of mental illnesses and allied disorders. Before discussing the help we need from the community, let us look briefly at the problems we face and the gains recently made.

We are all acutely aware of the mental institutional problem in this country. Despite the fact that the population of mental hospitals has begun to decline slightly within the past year or two, some three-quarters of a million people are still confined to institutions. It has not been long since the certification of an individual for and his admission to one of these public institutions characteristically marked his permanent departure from the family and the community. The walls around these institutions were high, and the people inside, staff as well as patients, had practically no communication with the world outside.

Three things have happened to these institutions in recent years.

First, a much more dynamic program of treatment has been initiated in most of them. Such new therapies as the tranquilizer drugs, which have curbed symptoms and made patients more amenable to other types of definitive treatment, have given impetus to this program.

Second, various forces have helped to tumble down the walls, so that the institutions have become a much more active part of their communities.

Third, the communities themselves have begun to grope toward efforts at preventing or at least retarding the hospitalization of those people who show signs either of aberrant behavior or of aberrant thinking.

There are other promising developments in mental hospitalization. We are learning that

the same way that we now control tuberculosis and other diseases. Such programs become more crucial when we consider the effects of improved methods of treatment and the increased emphasis on returning partially recovered patients to the community. For example, many patients may be able to return to the community in the first year or two after hospitalization, and many may be treated on an outpatient basis without ever being hospitalized. This depends, however, on the development of community resources, which are for the most part latent or nonexistent. As we in public health view it, the mental hospital is one of a whole complex of community agencies available to deal with mental and emotional disorders. It can provide professional assistance to other agencies, but needs their assistance to carry out its own mission successfully. The new trends make the community a key factor in the management of mental illness and should dramatically sharpen community awareness of the need for effective preventive work.

What then is the community like? How is it organized and how does it function?

The basic unit, in relation to our problem, is the family. Over and over again it is said that mental health efforts need to be directed to the family—its interpersonal relations, its child-rearing practices, its external attitudes. Families can be reached in a number of ways. We know, for example, that such communication media as newspapers, magazines, radio, and television reach many families at the same time. We also know that families coalesce in neighborhood groupings and in various groups around the school, the church, health agencies, and social and work interests. We know that families need help in child rearing, and that key agencies like the school, church and synagogue, Scouts, and Y's give this help.

Our knowledge of how communities build or retard sound mental health is still inadequate. But we have enough information to warrant trying out various preventive techniques. And it seems reasonable to presume that children, and families in relation to children, would be the most productive starting point in any long-range mental health program.

Almost all children go through the school system, where there is ample opportunity to

observe and influence their behavior. If the school is well staffed and equipped, its influence can be in the direction of better mental health. Most schools examine the child's health and confer with parents regarding illness or behavior problems. Some school systems employ psychologists, social workers, and other trained personnel to help in dealing with emotional problems that can best be handled within the school setting. Anyone who has worked in schools and in parent-teacher groups has felt the great striving toward mental health which parents have for their children and for themselves. The school is a powerful focus for mental health efforts.

There are other counseling and guidance services, including the courts and welfare agencies, which should be viewed as resources for mental health work. Even more important, perhaps, for basic preventive efforts are churches and synagogues, places of work, and social and neighborhood groups.

Opinion Leaders and Caretakers

In all communities there are two overlapping groups of people, called by some the "opinion leaders" and the "caretakers," who can contribute much to mental health efforts. The opinion leaders are those whose influence molds the opinions and behavior of a great many people. Political, religious, business, and professional leaders are in this category.

The caretakers are the people who are called on in time of psychological stress, such as bereavement, illness, and changes in job or social role. These situations can be quite critical for people who may need help to function normally. Caretakers who can administer such psychological "first aid" are, among others, physicians, clergymen, police, social workers, nurses, and teachers.

If it were possible to provide some kind of mental health training for the opinion leaders and the caretakers, these key people might be able to do a more effective job. Ultimately they might create a kind of therapeutic environment in the community and spread a "contagion of health." In the long run, such environments would tend to reduce the incidence of mental illness and permit the management and treat-

brain and central nervous system, about techniques for treating the mentally ill, and about preventive measures. Special emphasis is being given to such key problems as schizophrenia, alcoholism, mental retardation, and the use of psychopharmacologic agents in treating mental disorders. In a relatively new program, the Public Health Service makes funds available for demonstrations in new methods of treating and caring for the mentally ill.

The growth of community mental health facilities represents another great area of progress. Partly as the result of Federal and State encouragement, communities have begun new programs and services. Voluntary agencies and welfare groups, at all levels, have contributed substantially to this new look at mental health services.

But the task ahead is still a staggering one. Our basic knowledge is far from complete. We are not able to apply even the limited knowledge we do have. It is not likely that we will have all the psychiatrists and other professional personnel we need for many years to come. It is fairly certain that, for a long time at any rate, we will have to "make do" with facilities that are inadequate, in terms of both quality and quantity. All of these areas point up the extent to which the entire community must be involved.

Preventive Possibilities

As a nonpsychiatrist I am afraid I must confess to you that I am rather skeptical about much of what the psychiatrists hold out as effective psychotherapy or as effective prevention. I have unfortunately seen too many instances of exclusive and complete dependence on these resources and too many failures as a result. It is my own private opinion that the ultimate solution of the problems of mental illness lie more within the realm of biochemistry and psychopharmacology. At least in therapy I consider the analyses, the psychotherapeutic interviews, and all the other current techniques to be partially effective, much in the same way that a crutch or a cane is helpful to a person with a fractured leg bone and not much more likely to produce a permanent and successful cure.

As to prevention, I must admit I am not quite so strongly biased. I can accept the analogy which describes individuals as having varying amounts of insulation or protection surrounding the development of their "normal" thought processes and their "nerves." It is quite possible that this insulation can be strengthened by the provision of a wholesome mental milieu or environment for the individual, by the removal from the environment of those toxic factors which would eat away the insulation. Hence, just as a cane or a crutch is useful in preventing a broken leg when one is not quite as steady on his feet as most people or when one is forced to tread a precarious and slippery path, so improvement of the mental environment may be of significant benefit to the borderline individual or others faced by hazards.

The path can be smoothed, straightened, and made passable. This is the job of the community and its various agencies. If you were to draw a circle around the area which contains most of the factors affecting an individual's mental health, you would probably draw the circle around his community, recognizing, of course, that there are certain regional and national forces at work too. The community is the basic element in the mental health effort and even State and national agencies work best when they work closely with community mental health groups.

In only a few communities, however, are attempts being made to do a coordinated job in spite of the fact that lack of coordination means wasted time and effort. Bradley Buell and his associates a few years ago found that 6 percent of the families in a midwestern city were utilizing more than 40 percent of the community's social and health services of all types. For years Buell and his associates have been arguing for a unified effort by community health and social agencies. They suggest that only one agency assume primary responsibility for each family which presents multiple problems, and that this agency then coordinate the services of other agencies in a well-planned rehabilitation effort. To my knowledge this approach has not yet been fully tried anywhere.

Coordinated, long-range programs are essential if we are ever to control mental illness in

the same way that we now control tuberculosis and other diseases. Such programs become more crucial when we consider the effects of improved methods of treatment and the increased emphasis on returning partially recovered patients to the community. For example, many patients may be able to return to the community in the first year or two after hospitalization, and many may be treated on an outpatient basis without ever being hospitalized. This depends, however, on the development of community resources, which are for the most part latent or nonexistent. As we in public health view it, the mental hospital is one of a whole complex of community agencies available to deal with mental and emotional disorders. It can provide professional assistance to other agencies, but needs their assistance to carry out its own mission successfully. The new trends make the community a key factor in the management of mental illness and should dramatically sharpen community awareness of the need for effective preventive work.

What then is the community like? How is it organized and how does it function?

The basic unit, in relation to our problem, is the family. Over and over again it is said that mental health efforts need to be directed to the family—its interpersonal relations, its child-rearing practices, its external attitudes. Families can be reached in a number of ways. We know, for example, that such communication media as newspapers, magazines, radio, and television reach many families at the same time. We also know that families coalesce in neighborhood groupings and in various groups around the school, the church, health agencies, and social and work interests. We know that families need help in child rearing, and that key agencies like the school, church and synagogue, Scouts, and Y's give this help.

Our knowledge of how communities build or retard sound mental health is still inadequate. But we have enough information to warrant trying out various preventive techniques. And it seems reasonable to presume that children, and families in relation to children, would be the most productive starting point in any long-range mental health program.

Almost all children go through the school system, where there is ample opportunity to

observe and influence their behavior. If the school is well staffed and equipped, its influence can be in the direction of better mental health. Most schools examine the child's health and confer with parents regarding illness or behavior problems. Some school systems employ psychologists, social workers, and other trained personnel to help in dealing with emotional problems that can best be handled within the school setting. Anyone who has worked in schools and in parent-teacher groups has felt the great striving toward mental health which parents have for their children and for themselves. The school is a powerful focus for mental health efforts.

There are other counseling and guidance services, including the courts and welfare agencies, which should be viewed as resources for mental health work. Even more important, perhaps, for basic preventive efforts are churches and synagogues, places of work, and social and neighborhood groups.

Opinion Leaders and Caretakers

In all communities there are two overlapping groups of people, called by some the "opinion leaders" and the "caretakers," who can contribute much to mental health efforts. The opinion leaders are those whose influence molds the opinions and behavior of a great many people. Political, religious, business, and professional leaders are in this category.

The caretakers are the people who are called on in time of psychological stress, such as bereavement, illness, and changes in job or social role. These situations can be quite critical for people who may need help to function normally. Caretakers who can administer such psychological "first aid" are, among others, physicians, clergymen, police, social workers, nurses, and teachers.

If it were possible to provide some kind of mental health training for the opinion leaders and the caretakers, these key people might be able to do a more effective job. Ultimately they might create a kind of therapeutic environment in the community and spread a "contagion of health." In the long run, such environments would tend to reduce the incidence of mental illness and permit the management and treat-

ment of the less seriously ill right in the community.

Incidentally, we also need to locate the foci of infection in the community—individuals in places of influence who exercise a detrimental effect on the mental health of others. Unfortunately, these people also tend to be caretakers and opinion leaders.

Obviously, more work is needed to identify the key people in the community and to discover the type of training that is best suited for them. This approach, however, is worth pursuing. For one thing, we do not now have nor are we likely to have in the future enough professional mental health workers to do the preventive job that is needed. On the other hand, most communities contain a great reservoir of healthy, well-motivated people who are potential resources of preventive measures. These are the people who keep the wheels turning in the community and keep our complex social system working smoothly. They need to be alerted to spot incipient problems, to help prevent these problems if possible, and to handle deviant behavior in a constructive way.

We need also to deepen our understanding of the social significance of deviance. In a period of rapid change, certain kinds of non-conforming behavior are desirable. If everyone behaved according to expectations, we would very shortly stagnate. Community leaders and caretakers need to know how to deal effectively with the constructive deviant, with the gifted child or adult who can enrich our life, different though his behavior may be. Sometimes it is difficult to distinguish between such a person and someone whose behavior is likely to lead him in a vicious circle toward mental illness. The healthy community will give understanding and help to both types of deviants if it is to avoid becoming overburdened with an increasing number of frustrated, sick individuals.

The Cultural Climate

Finally, the size of the problem requires a great deal of self-help, that is, public education and guidance in sound mental health principles. Casefinding programs aimed at highlighting the individuals with specific emotional difficulties depend upon the dissemination of mental health

information and education for the community at large. Then, community mental hygiene clinics could serve as the focal points for anticipating and adjusting conflicts which may arise in normal relationships in the home, the school, and the workplace.

If the emphasis is on prevention, we can be spared from a situation such as one in Ohio where, as part of its program, the State helped support the establishment of community mental hygiene clinics. Far too often, in my opinion, the clinics, organized around a psychiatrist-director, viewed their primary function as diagnosis and therapy of mental illness on an outpatient basis. Within a matter of weeks, the directors were swamped with patients and could not accept new referrals. What is more important, they could reserve very little time for the more important job of providing psychiatric consultation to courts, welfare agencies, schools, and other agencies which deal with people and could use this kind of guidance in preventive and health promotional activities.

What we needed in Ohio—and what we need now throughout the country—are more mental health centers which are devoted exclusively to the work of prevention. Such centers are part of the community's total resources for better mental health, resources which include a great many agencies and groups. These resources need to be known, assessed, and used in a coordinated community undertaking.

I cite once again an experience in Ohio, this one in Franklin County. About a year ago the Franklin County Mental Health Association enlisted all the major elements of the community in a survey on the availability of community resources for mental health. One of the main findings of their survey report was that "good community mental hygiene is not the responsibility of specific mental health services alone, but is also a responsibility shared in part by all and especially by all agencies and individuals who work with people and provide services for people."

This, then, is our modern answer to spells and charms. It will take determination and hard work to exorcise the demons, even of our own day. But the job can be done and must be done if we are to create a healthier world for ourselves and the generations to follow.

Attrition in Psychiatric Clinics for Children

JACOB TUCKMAN, Ph.D., and MARTHA LAVELL, M.S.S.

THE PAST DECADE has seen an increase in the number of outpatient psychiatric clinics for children, yet facilities are not and may never be adequate to meet the need. Even if the necessary funds were available, recruitment of trained personnel would be difficult. Moreover, the increasing demand for psychiatric services as the public becomes more aware of their value may far outstrip future expansion of clinic facilities.

Without in any way minimizing the need for more psychiatric facilities, it may be well to ask whether present clinics are now being fully used in giving direct psychiatric services to children. There appears to be a large proportion of patients or parents acting for them who terminate contact with the clinic before service is completed. Karpe (1) reports an overall attrition rate (patient and parent termination of clinic contact) of 26 percent, and Anderson and Dean (2), of 31 percent. Simon (3) mentions a considerably higher rate, 53 percent, which is broken down into rate of termination at intake (21 percent) and during treatment (32 percent). Golden (4) reports 14 percent attrition at intake, and Gray (5) states that one third of the patients did not return after intake. Witmer (6) does not give an overall rate but mentions that more than half of the cases in treatment withdrew before service was completed.

With the exception of Anderson and Dean,

Dr. Tuckman is chief, section on psychological services, education, and standards, division of mental health, Philadelphia Department of Public Health, and associate in psychology in psychiatry, School of Medicine, University of Pennsylvania. Miss Lavell is a statistician with the division.

these and other investigators (7-9), using case history data or telephone followup contact, have concerned themselves with reasons for termination or with factors associated with attrition. The factors studied have included sex, age, occupation of father, number of siblings, and distance from the clinic, as well as more subjective items such as parental attitudes toward the child or toward treatment and the ability of the parent to express anxiety.

These studies of attrition and the factors associated with it, although useful in pointing up an important problem, have certain limitations. In general, the phase of the clinic process at which attrition occurred, whether intake, diagnostic evaluation, or treatment, is not indicated. Without such a breakdown of the data, it would be difficult for clinics to focus their efforts toward remedying the situation. Moreover, factors associated with attrition may vary from phase to phase. The rationale for inclusion or exclusion of cases in computing attrition rates is not always clear nor are the samples clearly defined. For the most part, the data are based on small samples of less than 100 cases. In the studies concerned with factors associated with attrition, it is difficult to interpret the findings since the data generally have not been subjected to statistical test.

The purposes of this study, designed to avoid the limitations mentioned above, are to estimate attrition rates at each phase of the clinic process and to investigate the relationship between attrition at each phase and a number of personal and social factors. The study was conducted by the division of mental health, Philadelphia Department of Public Health, in cooperation with the health division of the Philadelphia Health and Welfare Council.

The Study Sample

During the calendar year 1955, 1,813 children were admitted to 11 of 12 children's outpatient psychiatric clinics in Philadelphia. A clinic is defined as "a psychiatric outpatient service for ambulatory patients where a psychiatrist is in attendance at regularly scheduled hours and takes the medical responsibility for all the patients in the clinic. Clinics that have only a psychiatrist on call or as a consultant are not included. However, a clinic which has budgeted funds for employing a psychiatrist but is temporarily without one is included" (10). The 11 clinics served a varied number of patients. One had an intake of more than 800; two had an intake of about 250 each; three between 100 and 150 each; and five, less than 60 each. Of the last group, two had an intake of less than 10 each. The one clinic not included in this study had a very small intake.

From this group of 1,813 admissions, which represented almost all children receiving service through public or voluntary psychiatric clinics, 1,548 were selected for study of attrition. Of the 265 cases excluded from the study, 8 were patients for whom it was not possible to determine at what phase attrition occurred and 257 were patients who had been referred for special services. Twenty-eight of the latter were referred for consultation only, that is, usually a single interview with parent or social agency on the management of a particular child, and 229 came for diagnostic evaluation only, primarily at the request of private psychiatrists or hospitals.

Of the 1,548 patients, 67 percent were boys and 33 percent, girls. Seventy-five percent were white and 22 percent, nonwhite; in 3 percent of the cases race was not stated. Ages ranged from 1 to 17 years: 14 percent were under 6, 28 percent between 6 and 8, 23 percent between 9 and 11, 23 percent between 12 and 14, and 12 percent between 15 and 17 years of age. In 33 percent of the cases, the patient came from a home broken by separation or divorce or death of one or both parents. Thirty-two percent were Protestant, 23 percent Catholic, 29 percent Jewish, and 16 percent of other or not-stated religions.

Information about the father's occupation was not available in almost half the cases. The most that can be said is that the entire range of occupations was represented and that those in the professional, managerial, and proprietary occupations were at least equal to their proportion in the general population.

Referral sources were as follows: schools, 32 percent; parents, friends, and relatives, 20 percent; private physicians, 19 percent; hospitals and clinics, 17 percent; social agencies, 7 percent; courts, 3 percent; other sources and not stated, 2 percent.

By examination of the case record including case summary or concluding interview, data were obtained regarding outcome of contact at each phase of the clinic process (intake, diagnostic evaluation, and treatment): whether the case was terminated by the patient, terminated by the clinic, or continued into the next phase.

Operationally, a case was considered terminated by the patient when evidence in the case record indicated that the patient did not return to the clinic after breaking appointments or when the patient or his parent notified the clinic that he no longer wished to continue. In a very small number of cases the patient had moved from the city, been admitted to an institution, or died.

A case was considered terminated by the clinic when the patient was discharged because he had shown sufficient improvement; when the clinic had made other plans for the child, for example, referral to appropriate agencies in the community or, on occasion, to a private psychiatrist; when clinic policy made the child no longer eligible for service because of age or school dropout, or because long-term psychotherapy was indicated which the clinic was unable to provide; or when the clinic felt that further therapy was not indicated because the patient or responsible relative was not able to benefit from continued treatment.

Results

The data on outcome of contact with the clinic (table 1) showed that 31 percent of the cases were terminated by the patient and 4 percent by the clinic during or at the end of the intake phase; in 1 percent outcome was not stated. The majority, however, 65 percent

¹ Less than 0.5 percent.

(1,000 cases), moved into the diagnostic evaluation phase. Of these, 15 percent were terminated by the patient at some point in or at the completion of the diagnostic evaluation phase, while 11 percent were terminated by the clinic, and 4 percent had an unstated outcome. Again the majority, 70 percent (702 cases), moved into the treatment phase. Of these, 42 percent were terminated by the patient, and 26 percent were terminated by the clinic, 16 percent as improved, 5 percent referred to other agencies or services, and 5 percent for other reasons. The proportion of cases terminated by the

patient in the treatment phase is probably an underestimation because 14 percent were still in treatment, or awaiting treatment, and in 18 percent of the cases no information was available about outcome. Irrespective of phase, the overall attrition rate (patient or parent termination of clinic contact) was 59 percent of all clinic admissions.

The data given above for all clinics combined do not indicate the variation from clinic to clinic. Excluding clinics with an intake of less than 25 cases, the following variations were found among eight clinics. At the intake phase

the proportion of cases terminated by the patient ranged from none to 45 percent; those terminated by the clinic from none to 6 percent; and the proportion of cases that moved into the diagnostic evaluation phase ranged from 49 percent to 100 percent. At the diagnostic evaluation phase, termination by the patient varied from 2 percent to 34 percent; termination by the clinic from 2 percent to 20 percent; and the proportion that moved into the treatment phase varied from 40 percent to 96 percent. At the treatment phase patient termination varied from 10 percent to 55 percent, and clinic termination from 5 percent to 52 percent. The amount of patient termination at any one phase was not found to be significantly related to patient termination at any other phase. The attrition rate for all phases varied from 26 percent to 71 percent. The variation in attrition among the different clinics at any phase or all phases is probably due to a number of factors including type of clientele, length of waiting period, fee schedule, and clinic policy and procedure.

To determine what factors were associated with outcome of contact, comparisons were made at the intake and diagnostic evaluation phases based on the proportion of cases that were (a) continued, that is, moved into the next phase of the clinic process, (b) patient terminated, and (c) clinic terminated. In the treatment phase, comparisons were based on the proportion of cases that were patient terminated and clinic terminated. In this phase, the findings should be interpreted with caution since cases in treatment or awaiting treatment and those with unknown outcome were not included in the analysis.

Sex, race, and age were not found to be related to outcome at any phase of the clinic process, but certain other factors were significantly related: referral source, living arrangements of child, religious affiliation, number of problems presented, and distance from the clinic (table 2).

Referral source was related to outcome at the intake and diagnostic evaluation phases only. At the intake phase, referrals by social agencies and by hospitals and clinics were more likely to be continued and less likely to be patient

terminated than were referrals by other sources. At the diagnostic evaluation phase, the pattern was different. Although referrals by social agencies again showed the highest proportion in the continued and the lowest in the patient-terminated group, those by hospitals and clinics were next to the lowest in the continued and next to the highest in the patient-terminated groups. Referrals by parents, friends, and relatives, by schools, and by private physicians were among the highest in the continued and in the middle range in the patient-terminated group. Court referrals were least likely to be in the continued group and most likely to be patient terminated. Referrals by courts and by hospitals and clinics were highest in the clinic-terminated group while those by schools were the lowest.

Living arrangements of the child had a bearing on outcome of contact at the intake and treatment phases only. At the intake phase, children in institutions or foster homes were most likely to be in the continued group, whereas those in homes with a step-parent were least likely to be continued. At the treatment phase, the proportion of patient terminations was lower for children in institutions or foster homes than for those with any other living arrangement and highest for those living with relatives. The tendency for children in institutions or foster homes to carry through was not unexpected in view of the finding that social agency referrals hold up best.

Religious affiliation, studied for whites only, was associated with outcome of contact at the diagnostic evaluation phase only. A higher proportion of Jews than of Catholics or of Protestants were in the continued group; and Jewish contacts were least likely to be either patient terminated or clinic terminated.

The number of problems presented by the children, as reported usually by parents at the initial contact with the clinic, was associated with outcome of contact at each phase of the clinic process. The problems had been classified in 12 categories: anxiety and neurotic symptoms, severe psychiatric symptoms, withdrawal behavior, school problems, mental retardation, aggression, antisocial behavior, difficulties in interpersonal relationships,

² Based on whites only.

³ Expressed as categories.

⁴ Based on three largest clinics.

somatic symptoms, problems of habit formation, sexual problems, and miscellaneous.

Categories of problems, not the number of problems within the category, were analyzed. For example, if poor school work, truancy, and cheating were reported for one patient, he was treated as one individual presenting a school problem. In reporting the data, number of problems refers to number of categories. At the intake phase, children with three or more problems were less likely to be in the continued and more apt to be in the patient-terminated group than were those with less than three problems. At the diagnostic evaluation phase, however, the pattern was just the opposite. At the treatment phase, children with the most

problems were more likely to be patient terminated. It is recognized that the relationship between number of problems and severity cannot be established with any degree of accuracy nor can the combinations of problems be equated. Within the limitations of the data, however, patients presumably in greater need of psychiatric help were more likely to terminate contact than those in less need of help at both the intake and treatment phases.

It has been suggested that distance from the clinic affects attendance, that is, patients who must travel long distances to the clinic are less likely to maintain contact. Such opinion is not supported by the data. If anything, the relationship is just the opposite.

To determine the effect of distance from the clinic on clinic contact, only cases from the three largest clinics were studied because of complexities of analysis. Comparisons with respect to distance from the clinic were made in three ways. The first involved a division of the cases by residence in near and far health districts. (For administrative purposes, Philadelphia is divided into 10 health districts.) "Near" refers to the health district in which the clinic was located and those contiguous to it. "Far" refers to health districts farther removed. In the second comparison patients residing in the district in which the clinic was located were compared with those in all other health districts. The third comparison involved a division of the cases by residence in or outside the city.

At the intake and the treatment phases, no difference was found between the near and the far, or between the same and the other health districts. However, at both phases, city residents were more likely to be patient terminated than were nonresidents. It should be pointed out that some areas outside the city are closer to certain clinics than are some areas within the city. At the diagnostic evaluation phase, a higher proportion of those living in near districts than of those in far districts were patient terminated; the same tendency was found for the same and the other health districts.

The findings with respect to the factors associated with outcome of contact show variation at different phases of the clinic process. This is probably due in part to the increasing homogeneity of the clinic population as it moves from one phase to another, but also to changes in the situation within the family or the clinic during the months that may elapse between the initial clinic contact and the other phases.

It is most difficult to isolate the effect of specific factors on outcome since there is interaction among some of the factors. Moreover, other factors on which no information was available may have been operating. For example, socioeconomic level was undoubtedly a factor in the relationship between outcome and distance from the clinic since children living in the farther health districts or out of the city are more likely to come from a higher

socioeconomic stratum than those living in nearer health districts or within the city.

Discussion

This study of 1,548 patients admitted to 11 psychiatric clinics for children in a large city has shown a high proportion terminating contact before service was completed, especially in the treatment phase.

Even though the patient has terminated contact he may have received some benefit, and the family may have a better understanding of his problem and how to cope with it. In some cases, in the absence of more appropriate facilities, children may be accepted for treatment because of the severity of the problem, with full recognition that certain factors militate against a successful outcome. There may also be factors not wholly within the clinic's control that affect the attrition rate. One factor undoubtedly is a limited appreciation by the public of the nature of psychiatric treatment and the amount of progress to be expected in a given period of time. When a crucial problem has been resolved to some extent, thereby reducing tensions in the home, some families may terminate contact before the clinic feels it advisable. Another factor may be the cost of clinic service, which some families may consider too high because of other pressing demands on their income.

In the light of present knowledge and the public's attitude toward psychiatry, it may be that a high attrition rate cannot be avoided. However, in the absence of adequate data such a conclusion cannot be considered valid. Although this study provides data about certain factors associated with attrition, more information, collected on a systematic basis, is needed regarding not only the personal and social characteristics of patients who terminate contact but also the more subtle motivational factors that affect clinic attendance. Research of this kind will provide the basis for further refinement of criteria for selection of patients and of procedures for reducing the attrition rate. Since the magnitude of the problem varies from phase to phase among the different clinics, each clinic needs to determine for itself, by an examination of the caseload, at what point in the process efforts should be focused.

Trial of Drugs for Gout

Zoxazolamine is undergoing clinical trial for the treatment of gout at the National Institute of Arthritis and Metabolic Diseases, Public Health Service.

Zoxazolamine has been used for several years as a muscle relaxant. Its possibilities in the treatment of gout were noticed in studies of the drug's metabolic breakdown in the body, during which large amounts of uric acid crystals were observed in patients' urine.

The original studies were made by Dr. J. J. Burns of the National Heart Institute and research workers at the Mount Sinai and Goldwater Memorial Hospitals in New York City, under a grant from the National Institute of Arthritis and Metabolic Diseases.

Dr. J. E. Seegmiller of the institute's Arthritis and Rheumatism Branch is directing a larger and more intensive clinical trial of

zoxazolamine. To date studies have shown that the drug is approximately six times more potent than other uricosuric drugs.

Another uricosuric drug, sulfinpyrazone, is also being studied at the institute. The two drugs given together appear to produce greater uric acid excretion than either singly.

Gout affects approximately 300,000 persons in this country. Usually the first sign of this arthritic disease is excruciating pain and swelling. Attacks recur at irregular intervals.

A disturbance in body chemistry which results in an increase in the amount of uric acid in the blood and tissues is associated with both chronic gout and acute gouty arthritis. The uric acid is often deposited in cartilage, and in time the deposits grow until they form masses of chalky uric acid salts.

Use of general hospitals

Variation With Methods of Payment

MAURICE E. ODOROFF, M.A.

LESLIE MORGAN ABBE, B.S.

A STUDY of the use of general hospitals has included an investigation of the variation in levels of use in relation to methods of payment for hospital care and in relation to existence of prepayment coverage. This variation has also been examined in relation to selected personal and economic factors. Data were collected in September 1956 through interviews of about 27,000 households, including about 90,000 persons of all ages, drawn from the civilian noninstitutional population of each State. Selected highlights of the findings on these relationships are reported here.

From each family a history was obtained of hospitalizations during the previous 12 months. This history covered each admission of each member of the household, with length of stay, reason for admission, identification of the hospital, and method of paying the hospital bill. Since the survey was conducted in connection with the monthly Current Population Survey of the Bureau of the Census, data on selected personal characteristics were available for the

members of each household. Income data were obtained by a special question in the survey. Information was also elicited about insurance or other prepayment plans covering the cost of hospital care. This part of the interview was facilitated by a previous letter to each family asking them to be ready to supply such information.

Instructions to enumerators contained two principal definitions. The "hospital bill" was defined as "all charges made by the hospital and charges by surgeons, anesthetists, special nurses, or others engaged by the patient for service in the hospital." "Hospital prepayment coverage" was defined as including the following hospital insurance and medical care plans:

1. Commercial hospital insurance (when not limited to accidents), on either individual or group basis.
2. Blue Cross or Blue Shield plans or other nonprofit plans sponsored by medical societies, on either individual or group basis.
3. Consumer-sponsored plans (not types 1 and 2) which provide prepaid hospital care, including cooperatives and plans sponsored by fraternal organizations.
4. Industrial plans of an employer or union which provide hospital care beyond that legally required for industrial accidents.

Mr. Odoroff is chief and Mr. Abbe is assistant chief of the Program Evaluation and Reports Branch, Division of Hospital and Medical Facilities, Public Health Service.

This is the third interim report of provisional findings from a national household survey of the use of general hospitals. The first, published in the May 1957 issue of *Public Health Reports* (pp. 397-403), briefly described the survey procedure and presented findings on demographic and ecologic factors in the use of inpatient facilities. The second, published in the June 1957 issue of *Public Health Reports* (pp. 478-483), presented findings on demographic, ecologic, and economic factors in the use of outpatient facilities. Analysis and interpretation of all data and comparison with other studies will be included in a summary monograph when the tabulations are completed.

The survey is considered a first step in defining more precisely appropriate standards of need for general hospitals in the light of changing medical practice and changing patterns of care. It is expected to point the way to more intensive studies of the real need for physical facilities for adequate care of a known and described population. The survey was conducted for the Division of Hospital and Medical Facilities of the Public Health Service in September 1956 by the Bureau of the Census, in connection with its monthly Current Population Survey.

5. Other free or reduced-cost hospital plans, such as hospital employee benefits, free care for dependents of Armed Forces members, and the like.

Particular effort was made to include only insurance or plans that were general in extent and to exclude those for particular purposes or of uncertain availability. Not included as hospital prepayment coverage were (a) policies covering only accidents, "dread diseases," income lost from disability, clinic or office visits, or liability for injury to others, or (b) free hospital care for veterans in Veterans Administration hospitals.

The reports of hospitals used were screened to avoid counting time spent in long-term hospitals or nursing homes. All available inventories and registers were consulted for this purpose.

The data collected have certain limitations, since they do not cover institutional popula-

tions or persons who were hospitalized during the 12-month period but who died, moved, or entered the Armed Forces before the survey was taken. Members of the Armed Forces were not enumerated, although other persons in the same household were included. In addition, reporting and tabulating difficulties made it necessary to confine a portion of the study to persons 14 years old and over. A summary monograph, to be published after the interim reports are concluded, will contain an appraisal of under-reporting in the survey, and will also discuss measures of sampling variability and the problems of errors of response. (Some comments on these matters were included in the second interim report.)

Methods of Payment

The following four methods of payment were identified in the survey:

Prepayment plan: Any part of the hospital bill paid by hospital insurance or a medical care plan (see definitions above).

Self or relatives, or both: Any part of the hospital bill paid by the patient or his relatives, including those living outside his household.

No charge made: Free care, either in a public hospital (city, State, or Veterans Administration) or in one supported by private, charitable, or community chest funds, and including hospitalization cost paid directly by public assistance or relief agencies.

Other methods: Cost met in some way not included in first three classes, such as assistance by friends, payments by employer without any regular medical plan or under workmen's compensation, insurance payments under driver's liability when hit by automobile.

These methods occurred singly and in combination. The most frequent combination reported was that of prepayment plan plus payment by self or relatives. Other combinations were infrequent. Accordingly, hospital use has been tabulated under the four single methods of payment and also under the principal combination.

Three measures of the level of hospital use were employed throughout the study: (a) annual admissions per 1,000 population, (b) annual patient-days per 1,000 population, and (c)

Table 1. General hospital use, by age and method of payment for care

NOTE: Discrepancies in totals result from rounding.

average stay per admission. These measures of use have been compiled under each method of payment for care according to the patient characteristics of age, family income, and reason for admission.

Age has a considerable influence on the level of hospital use, regardless of the method of payment for care (table 1). In general, as age increases, so does the annual number of patient-days under each of the several methods of payment. However, when hospitalization is paid for by a prepayment plan alone, the rate of

patient-days reaches a peak at ages 25-34 years and then declines through ages 45-54. A new peak is reached at the ages 55-64 years, with a second decrease for persons 65 and over.

The average stay also rises steadily with age. It accelerates much more rapidly when care is free than when it is covered by any other method of payment. Free-care patients aged 55 to 64 years and those 65 and over were hospitalized for averages of 30 and 32 days per admission, or more than twice the average stay of all persons at these ages.

Table 2. General hospital use, by members of primary families,¹ by family income and method of payment for care

¹ Primary families include persons related by blood, marriage, or adoption (one of these being the head of the household). ² Less than 0.5.

NOTE: Discrepancies in totals result from rounding.

Family income appears also to affect the level of hospital use under each method of payment (table 2). Admissions paid for by prepayment plans rise rapidly with family income to the \$5,000 level, remain stable until the \$7,500 level, and then decline slowly. Families with in-

comes below \$1,000 pay for nearly one-half of all their admissions and patient-days through their own resources alone. Families with incomes between \$1,000 and \$3,000 have the highest rate of hospital use as measured in patient-days per year.

Table 3. General hospital use, by reason for admission and method of payment for care

Other reasons.....	9.3	7.7	8.6	7.7	20.8	14.6

¹ Less than 0.5. NOTE: Discrepancies in totals result from rounding.

Reasons for admission, with the exception of obstetrics, seem not to have much effect on hospital use in relation to the different methods of paying for care (table 3). For obstetrical care, 30 percent of all patient-days were paid for solely by the family, as compared with 20 percent for all reasons for admission. For each reason for admission except obstetrics, average stay was less under prepayment plans, either when they were the sole method of payment or when they were supplemented by family resources, than the average stay for all persons. Average stay under free care was much longer than care covered by other methods of payment for all reasons for admission except obstetrics and "other reasons."

Prepayment Protection

As a supplement to the tabulations on methods of payment, tabulations have been developed to show contrasts in use between patients having some prepayment protection and those having none. These tabulations exclude children under the age of 14 years, for whom data were incomplete. They relate only to the population receiving hospital care, not to the population as a whole. In obtaining data on types of prepayment protection, the enumerators identified and reported only the most comprehensive plan for persons who had two or more plans.

The type of prepayment plan and the type of coverage are both related to the level of hospital use (table 4). Persons with at least some pre-

Table 4. General hospital use among persons 14 years old and older, by prepayment protection status and type of coverage

¹ Includes Blue Shield plans.

payment protection (regardless of its comprehensiveness) make more frequent use of hospitals than those without any protection. For the population 14 years of age and over, the annual admission rate for those with prepayment protection is 135 per 1,000 population; for those without protection it is 93 per 1,000 population. Average stay per admission, however, is lower for those with protection (7.7 days) than for those without it (10.8 days). Consequently, the number of patient-days per 1,000 population is about the same for both groups.

Persons with Blue Cross protection are admitted to hospitals at the same rate as those protected under other plans. (In this study the term "Blue Cross" includes Blue Shield plans as well, and is used in referring to either type of plan or both types.) They stay considerably longer, however, and thus use more patient-days: 1,131 per 1,000 population as compared with 953.

Substantial differentials appear in the level of use as measured by annual patient-days under

¹ Data not available.

different types of coverage. The level of use was lower when prepayment protection covered hospitalization alone or hospitalization and surgery than when coverage consisted of "other combinations." Coverage for hospital and surgical costs results in a shorter average stay than does hospital coverage alone.

¹ Primary families include persons related by blood, marriage, or adoption (one of these being the head of the household).

² Includes Blue Shield plans.

NOTE: Discrepancies in totals result from rounding.

In each age group, persons with prepayment protection have a higher admission rate than do those without protection (table 5). However, their average stay is shorter, particularly in the older groups, and consequently there is less difference in the number of patient-days.

To examine hospital use rates in relation to family income and prepayment protection status, rates have been computed on two separate bases: (a) total population in each income group and (b) population in each protection status in each income group.

Table 7. General hospital use by members of primary families¹ 14 years old and over, by family income, prepayment protection status, and type of prepayment coverage: Rates based on population in each protection status in each income class

Family income	All members				Members without prepayment protection
		All members covered	Covered by Blue Cross ²	Covered by other plans	
Annual admissions per 1,000 population					
All incomes	122	137	136	139	94
Under \$1,000.....	105	127	129	126	100
\$1,000-\$1,999.....	120	166	194	148	95
\$2,000-\$2,999.....	138	170	187	159	105
\$3,000-\$3,999.....	133	150	156	145	100
\$4,000-\$4,999.....	137	152	146	158	92
\$5,000-\$7,499.....	120	129	126	132	84
\$7,500-\$9,999.....	102	107	101	115	75
\$10,000 and over.....	91	97	100	92	69
Income not reported.....	116	138	135	139	82
Annual patient-days per 1,000 population					
All incomes	986	1,040	1,125	954	885
Under \$1,000.....	1,047	982	1,466	714	1,063
\$1,000-\$1,999.....	1,196	1,364	2,001	947	1,107
\$2,000-\$2,999.....	1,249	1,486	1,946	1,165	1,016
\$3,000-\$3,999.....	1,056	1,143	1,256	1,044	892
\$4,000-\$4,999.....	915	1,015	1,049	981	630
\$5,000-\$7,499.....	896	952	952	952	663
\$7,500-\$9,999.....	755	789	845	717	595
\$10,000 and over.....	852	886	980	735	720
Income not reported.....	971	1,091	1,161	1,002	770

¹ Primary families include persons related by blood, marriage, or adoption (one of these being the head of the household).

² Includes Blue Shield plans.

The first series of rates permits study of the magnitude of the components of total use within each income group, according to prepayment status (table 6). On this basis it appears that hospital use, in patient-days, by families with low incomes (below \$2,000) is largely without protection. Families with incomes above \$4,000, on the other hand, have prepayment protection for most of their hospital use.

Table 7 permits study of the specific levels of use by families in each protection status at each income level. It shows that both admissions and patient-days are greatest for low-income families, regardless of protection status, and that they decline steadily in the middle-income and upper-income ranges. Families with incomes below \$4,000 with Blue Cross pro-

tection use hospitals at a notably higher rate than do other families in these income groups, with a maximum of 2,000 annual patient-days per 1,000 population, as compared with about 1,100 patient-days for those with other types of plans or not covered.

Summary

Data on use of general hospitals, obtained in a national household survey of about 27,000 families, with 90,000 persons of all ages, reveal the following variations with different methods of payment for care:

1. Hospital use rises rapidly with age when costs are met by a prepayment plan plus personal payments, personal payments alone, or free care, but hospitalization paid for by a pre-

payment plan alone shows no net increase in the rate of patient-days after age 34 years.

2. Patients aged 55 years and over for whom no charge is made have an average stay of 1 month, twice the average stay for all admissions.

3. Families with incomes under \$3,000 pay for about one-half of their hospital care through their own resources or else have free care.

4. When care is paid for by a prepayment plan plus family resources, annual patient-days rise as family income increases.

A comparison of hospital use with prepayment protection and use without it, for the population 14 years of age and over, shows the following highlights:

1. Prepayment protection is associated with more admissions and more patient-days per 1,000 population.

2. At all ages, persons with prepayment protection have a higher admission rate but a shorter stay than those without protection.

3. Low-income families (under \$1,000) without prepayment protection have substantially more admissions and more patient-days than do similar families with protection, while the reverse is true at higher income levels.

4. Families with incomes below \$4,000 who have Blue Cross protection use hospitals at a notably higher rate than all other families in this income range.

Selwyn D. Collins, 1891-1959

Dr. Selwyn D. Collins, on the staff of the Public Health Service since 1920, died March 24 in Boston. An innovator in public health research techniques, he was chief of the Division of Public Health Methods' Morbidity and Health Statistics Branch for nearly two decades. His work included participation in the Hagerstown Morbidity Studies, the Committee on the Costs of Medical Care, the first National Health Survey, and the survey of the Eastern Health District of Baltimore in which the Public Health Service, the Milbank Memorial Fund, Johns Hopkins University School of Hygiene and Public Health, and the Baltimore City Health Department collaborated.

In 1930 Dr. Collins began his studies of excess mortality associated with epidemics of influenza. He showed that mortality from other causes also increased during epidemics.

Beginning in 1938 Dr. Collins served on three decennial conferences for the revision of the International List of Causes of Death and assisted in developing the combined morbidity and mortality code for classification of diseases

now in use by member nations of the World Health Organization. He was chairman of the Index Subcommittee for the 1948 edition of the International Statistical Classification of Diseases, Injuries, and Causes of Death. Also, in the international field, he worked with the International Health Organization of the League of Nations and was a member of the WHO Expert Committee on Health Statistics. He was consultant on vital statistics to the occupation government in Japan, and, recently, a delegate to the Second International Statistical Congress, Bogotá, Colombia.

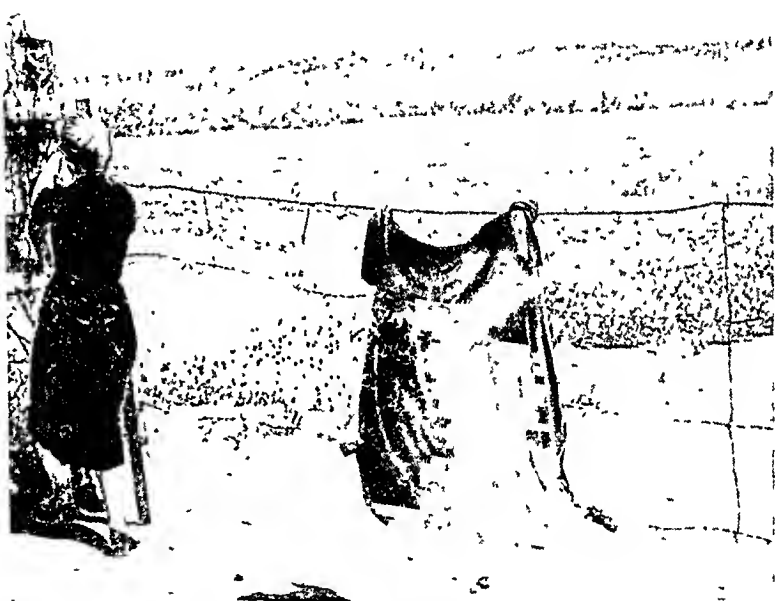

In conjunction with the editors of the 1952 edition of the Standard Nomenclature of Diseases and Operations, he directed the conversion of diagnoses to ISC categories.

A Fellow of the American Public Health Association, Dr. Collins served for 2 years as chairman of the statistics section. He was a member of the American Epidemiological Society and of the Washington Academy of Sciences.

Public Health Nursing for

MONTANA INDIANS

Two public health districts in Montana provide public health nursing services for Indian families living within the boundaries of three reservations. Under a contractual agreement between the Montana State Board of Health and the Division of Indian Health of the Public Health Service, Public Health District I (Big Horn and Rosebud Counties) at Hardin serves the Indians on the Cheyenne and Crow Reservations, and Public Health District II (Lake and Sanders Counties) at Polson serves the Flathead Reservation. Four other reservations in Montana are served directly by the Division of Indian Health.

Complicating the tasks of the local health departments are empty stretches of land and the mobility of the people. The prairies are sparsely settled, with 1 to 3 people per square mile, and crossed only by obscure trails and endless miles of fencing in which gates are invisible unless hung with an old coat or blanket (see photograph). Families migrate to higher land in summer or move in with more fortunate friends or relatives, leaving children to the care of neighbors or relatives.

The location of the homes and ranches of the Indians and non-Indians in the two districts makes cooperative health services feasible. Unlike the Navajo and other tribes who live apart

on tribal lands, Montana Indians and non-Indians in these two districts live side-by-side in the towns and on the ranch lands.

In both districts the Indians comprise substantial minorities of the total population. District I has a population of about 18,000 of whom 4,000 are Indians, and District II contains 21,000 people, including 2,000 Indians. Furthermore, Indians who receive the same kind of public health nursing services from the same agency as the rest of the citizens may be encouraged to participate in other aspects of the regular life of their communities.

The local health departments use the same personnel to serve the Indian and non-Indian

residents. The only difference is that the Indians, because of the magnitude of their health problems, require a higher ratio of personnel per population and more concentrated services. Indian health needs are estimated to be 10 to 13 times greater than those of others in the same area. Currently, each local health staff is organized to include a full-time health officer, public health nurses, sanitarians, health educators, and office clerks.

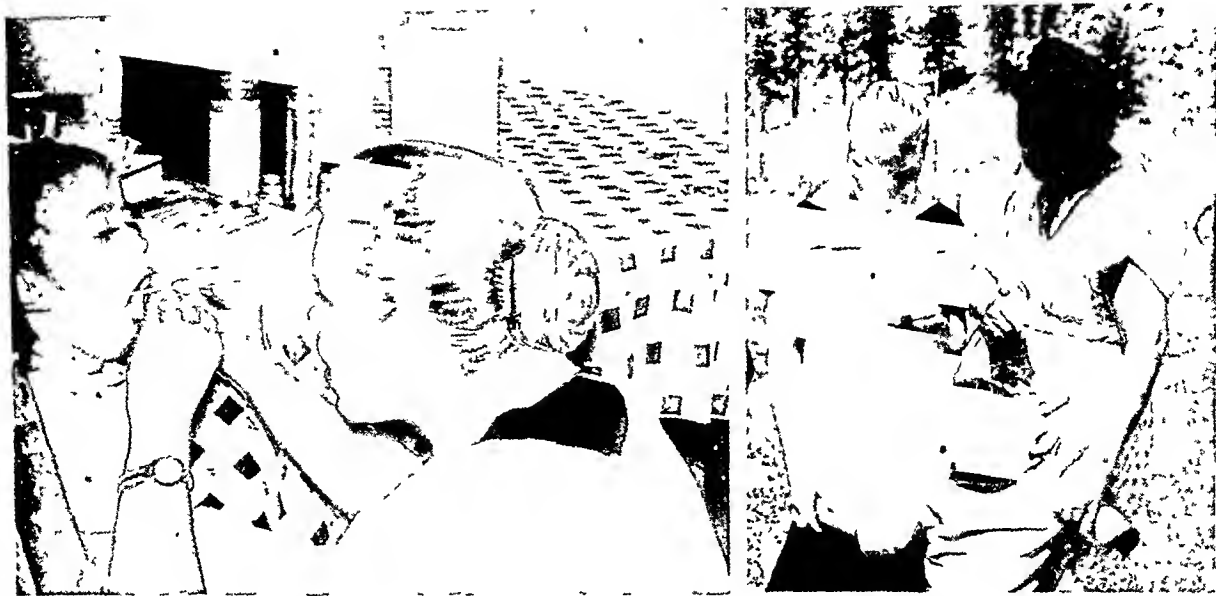

Collaborating on the picture story were these officials of the Montana State Board of Health, Helena: G. D. Carlyle Thompson, M.D., M.P.H., acting executive officer; Wava L. Dixon, director of public health nursing; and K. Elizabeth Anderson, director of public health education; and these staff members of Public Health District I: at Hardin, the late Elizabeth Bishop, M.D., M.P.H., health officer; and Doris G. Chandler, health educator, who took the photographs; and at Forsyth, Andre Pederson Gulvas, public health nurse.

Chatting with a man whose wife has tuberculosis, the nurse sets a date for his chest X-ray. The Indian death rate for the disease is high.

When a child is very ill and an isolated family cannot wait for a doctor, the nurse may give emergency service, plan for transportation, or take the family to medical or hospital care.

Left: Taking throat cultures or other evidence to a physician is part of the nurse's job in control of communicable disease. *Right:* For a sick child she improvises isolation techniques in a one-room cabin, then takes the quarantined family's grocery list to the store.

Left: On a school visit the nurse finds the slide needs repairs. *Right:* An Indian girl, torn between "living like others" and love of family, finds the nurse a friendly counselor.

Visceral and Cutaneous Larva Migrans

PAUL C. BEAVER, Ph.D.

AMONG ANIMALS in general there is a wide variety of parasitic infections in which larval stages migrate through and sometimes later reside in the tissues of the host without developing into fully mature adults. When such parasites are found in human hosts, the infection may be referred to as larva migrans although definition of this term is becoming increasingly difficult. The organisms implicated in infections of this type include certain species of arthropods, flatworms, and nematodes, but more especially the nematodes.

As generally used, the term larva migrans refers particularly to the migration of dog and cat hookworm larvae in the human skin (cutaneous larva migrans or creeping eruption) and the migration of dog and cat ascarids in the viscera (visceral larva migrans). In a still more restricted sense, the terms cutaneous larva migrans and visceral larva migrans are sometimes used to denote the formation of lesions due to a particular species of larva known or presumed to be the one most commonly involved: *Ancylostoma braziliense* in the skin, and *Toxocara canis* in the viscera. This usage of the terms is incorrect, however, since, as previously emphasized, the character and location of the lesions and the resultant symptoms are unreliable clues in the specific identification of the causative organisms (1).

Development of Concepts

The various groups and species of worms involved in the larva migrans type of infection, the clinical features of the diseases caused by them, and certain biological aspects of the host-parasite relationships have been discussed in a number of recent reports and reviews (2-5).

In the development of our concepts of larva migrans there have been four major steps. The first, of course, was the discovery by Kirby-Smith and his associates some 30 years ago of nematode larvae in the skin of patients with creeping eruption in Jacksonville, Fla. (6). This was followed immediately by experimental proof by numerous workers that the larvae of *A. braziliense* readily penetrate the human skin and produce severe, typical creeping eruption.

From a practical point of view these demonstrations were perhaps too conclusive in that they encouraged the impression that *A. braziliense* was the only cause of creeping eruption, and detracted from equally conclusive demonstrations that other species of nematode larvae have the ability to produce similarly the progressive linear lesions characteristic of creeping eruption. While in the initial studies by Kirby-Smith it was possible to demonstrate larvae in 10 percent of the skin biopsies from individuals with creeping eruption, no spontaneous case of cutaneous larva migrans has yet been given a specific etiological diagnosis; that is, no larvae have been identified in human skin.

For many years after it was shown that nematode larvae cause creeping eruption it was assumed that the apparently aimless migration was due to abnormal host-parasite relationships and that the larvae eventually perished and

Dr. Beaver is professor of parasitology, department of tropical medicine and public health, Tulane University School of Medicine, New Orleans, La. This paper was presented at the Communicable Disease Center's Conference for Teachers of Veterinary Public Health and Preventive Medicine, and Public Health Workers, Atlanta, Ga., June 12-18, 1958.

were destroyed in the skin. Two significant early observations argued against that view. Wright and Gold's finding of pulmonary infiltrations during or following the active phase of creeping eruption suggested that at least some of the larvae succeeded in making the normal migration to the lungs (7). It was also noted, however, that the pulmonary infiltrations could have resulted from the larvae without their having left the skin. Evidence of a more convincing nature was provided by the report of an authenticated intestinal infection of *A. braziliense* in a boy in Texas (8). If adults could be found in the intestine, the larvae must have migrated from the skin through the lungs enroute to the intestine. That record is no longer accepted, however, and the reports of intestinal infections of *A. braziliense* in man in other parts of the world have likewise been rendered doubtful by the observations that a morphologically very similar species, *Ancylostoma ceylonicum*, formerly regarded as a synonym of *A. braziliense*, is a valid species (9). An observation by Muhleisen was, therefore, of special significance (10). For a period of 24 days he found large numbers of larvae in the sputum of a man with severe and extensive skin lesions, leaving no doubt about migration from the skin to the lungs. Unfortunately the larvae were not identified, but it was determined without any doubt that a mature intestinal infection did not develop in this case.

Second Step

The second major event in the study of larva migrans came in 1952 with the discovery and identification of *T. canis* larvae in liver biopsies from children with a common disease which up to that time had been given a number of different names but was of unknown etiology (11). This was followed a year later by an experimental demonstration of the etiological role of *T. canis* (12) and by numerous confirmatory reports indicating that this common ascarid of dogs is responsible for much illness in children here and in other parts of the world and that it apparently is an occasional cause of death (13).

Biopsy and autopsy studies in children, and various types of studies in experimental ani-

mals have provided more interesting facts about *T. canis* as a cause of the visceral type of larva migrans than can be mentioned here.

Briefly, it has been established that infection is acquired by ingesting soil previously contaminated by infected dogs. Eggs passed in the feces, under favorable conditions in the soil, become infective in 2 to 3 weeks, containing second-stage larvae which, when taken into the intestine of a child, erupt from the egg, penetrate the intestinal wall, and soon reach the liver. A majority of the larvae may remain in the liver but others pass on to the lungs and to other parts of the body. Larvae have been found in nearly all organs. It is of chief interest that a high proportion of them invade the central nervous system and a considerable number have been found in the eye. The tragic consequence of invasion of the eye is the development of a lesion which by its resemblance to retinoblastoma prompts the unnecessary removal of that vital organ.

Although most of the larvae eventually come to rest in one location and stimulate fibrous encapsulation, there is a period of at least several weeks during which they move about in the tissues of the visceral organs in much the same manner as hookworm larvae migrate in the skin, leaving in their wake long trails of inflammatory and eosinophilic granulomatous reactions.

Thus in comparison with their microscopic size the wandering larvae produce large and extensive lesions that can be readily seen with the unaided eye in and on the surface of the liver and, at times, in other organs, especially the brain. This is the type of infection now called visceral larva migrans. Its most prominent clinical feature is high, stable, and persistent, eosinophilia, not uncommonly reaching levels suggestive of eosinophilic leukemia. Less outstanding and less constant features are enlargement of the liver, hyperglobulinemia, intermittent fever, infiltrations of the lungs, neurological symptoms, and deviations in behavior.

Thus far *T. canis* is the only species of larva identified in cases of visceral larva migrans. However, there is a good experimental and epidemiological basis for suspecting other species to be similarly involved. *Toxocara cati*, as common or more so in cats as *T. canis* is in

dogs, should occasionally reach the tissues of children. In one instance a larva in a child's liver has been questionably identified as *T. cati* (14).

Greatest anticipation of early incrimination is with *Ancylostoma caninum*. This worm is more common in dogs than *T. canis*, and occurs in cats as well as dogs. Whereas *T. canis* is relatively uncommon in older dogs and is especially uncommon in sexually mature females, *A. caninum* is found in both dogs and cats at all ages. Both parasites take full advantage of prenatal infection in maintaining a high level of endemicity and both are known to persist in the tissue of experimental animals for more than a year. There is no apparent reason why the larvae of *A. caninum* should not be found in the tissues of children along with the *Toxocara* species. However, further studies may bring to light an explanation which is presently not apparent. Larvae entering the body through the skin are less apt to be found in the liver and it is probable that *A. caninum* larvae are much less frequently ingested than the eggs of *Toxocara* and some of the other helminths.

The searching of liver biopsies for *Toxocara* larvae has in recent years uncovered three cases of *Capillaria hepatica* which formerly was found only at autopsy and was thought to be rare in man. It is hoped that when nematode larvae are encountered in the examination of human tissues it will not be assumed on circumstantial evidence that they are any particular species but rather will be identified on the basis of characteristic morphology.

Third Step

The third notable contribution to our knowledge of larva migrans came from a series of studies on the basic life cycle patterns among the ascarids. Sprent (15) summarized these studies and pointed out that while infections by some and perhaps most of those species adapted to carnivorous land mammals can be transferred from host to host in the same manner as *Ascaris lumbricoides*, that is, by ingestion of infective eggs in contaminated soil, the usual pattern under natural conditions includes intermediate or transport hosts.

Originally our domesticated dogs and cats

may have acquired their ascarid and perhaps some of their hookworm infections not directly from the soil but indirectly by eating other mammals which by feeding on the ground had earlier picked up the infective stages, preserved or further incubated them in their tissues, and passed them on to their predators.

Experimentally, *T. canis*, *T. cati*, and *A. caninum* can be transferred to their final host by first inoculating mice or other small mammals which are then after several days, weeks, or months fed to dogs or cats. The significance of such observations is immediately apparent. They point out that our previous interpretation of larva migrans caused by these species was essentially incorrect. The migration and persistence without development in human tissues are not, as we had supposed, basically due to an abnormal host relationship. We may still regard man as an abnormal host for the adult stage, and an unnatural host for the larvae in that he provides no advantage for the parasite as a species, but the behavior of the larvae in man being the same as in natural transport hosts apparently is not abnormal. It is then to be expected that any of the larval stages of nematode parasites of wild or domesticated carnivorous animals adapted to the use of mammalian intermediate or transport hosts may grasp the opportunity to enter the tissues of human hosts and await, unsuccessfully of course, the transfer to a predator final host.

It is obvious from these remarks that detailed studies on the life cycles of all worm parasites of animals having contact with humans have great usefulness in the study of larva migrans and other zoonotic helminthiasis.

Fourth Step

The fourth major advance in larva migrans research was Nichols' demonstration of the feasibility of identifying nematode larvae in microsections of tissues (16, 17). These classic morphological studies, while limited to only a half dozen species considered most likely to be encountered in human tissues, left no doubt that descriptions of these and other species could be sufficiently detailed to permit reliable identification often when only fragments of the larvae are available for study. The interpretation,

prevention, and effective control of any parasitic disease are, of course, dependent upon the accurate identification of the organism which causes it. To make this possible, additional studies such as Nichols' are needed.

Research on Prevalence

Inasmuch as public health programs place strong emphasis on the reliable determination of disease prevalence and on the development of preventive measures, we should mention here two additional phases of research in which recent studies show promise of providing important, useful information.

Thus far it has not been possible to get a clear picture of either the extent or the prevalence of visceral larva migrans. Originally, diagnosis was based on liver biopsies taken by laparotomy. This procedure is too hazardous and expensive to be used routinely. Furthermore, no specific therapy is available, and usually when additional infection can be prevented, the prognosis is favorable. It is understandable, therefore, that a clinical diagnosis, unconfirmed by actual identification of the causative organism, is relied upon in the management of most cases. It is equally understandable that unconfirmed clinical diagnoses are not really satisfactory.

In view of these circumstances, it is of great interest that promising and already somewhat useful serologic techniques of diagnosis are being developed by Sadun and associates (18), Kagan (19), and Jung and Pacheco (20). The fault in serodiagnostic methods has been their lack of specificity due to cross-reacting antigen-antibody systems among related worms. By fractionation and purification of antigens, cross-absorption of antibodies, and application of the recently developed hemagglutination and flocculation tests apparently reliable diagnoses are now being obtained.

With the recognition that dog and cat parasites cause obscure, serious disease in humans, surveys to determine the geographic distribution and prevalence of individual species have taken on new significance. Among the first to recognize this and to carry out a thorough and meaningful survey of dog parasites were Donaldson and his associates (21) and Ehrenford (22).

Ehrenford has given at least a partial answer to one of the first and most significant questions asked about *T. canis*. Recognizing that pups are more often infected than adult dogs the question is often raised as to the actual risk with older dogs. Ehrenford's answer is that the risk depends upon the sex of the dog. Males are about as frequently infected as pups but the incidence among females is lower at all ages and is markedly lower in the mature adult. In Indiana and adjacent States less than 5 percent of mature females were found to be infected, while almost a third of the mature males were passing *Toxocara* eggs that might eventually be the cause of illness in children. These data were obtained from stray, uncared for, unwanted dogs, as has been the case in almost all published surveys.

Studies in New Orleans indicate that although the rate of infection among well cared for dogs is relatively much lower, it still is disturbingly high. Among 171 fresh dog stools collected along the sidewalks in front of houses of perhaps the most sanitation-minded, hygiene-conscious, and economically most favored families in the city, 7 percent contained *T. canis* eggs; hookworm eggs were found in 51 percent, and *Trichuris* in 25 percent. Almost all of these stools were judged to have come from adult dogs.

Also in New Orleans, among 103 immature and 222 mature dogs brought to veterinarians for various services, all relatively expensive (indicating the owners' concern for their well-being), *Toxocara* was found in approximately 15 percent of the young dogs and 3 percent of the older ones (23). Relatively few of the dogs of either age group were presented specifically for anthelmintic treatment. Nearly half of them harbored hookworms and one-fifth had *Trichuris* infections.

Conclusion

There is much needed information to be derived from good surveys and epidemiological studies of intestinal parasites of dogs and cats. To be of greatest usefulness such studies should be carried out with the same careful preparation and epidemiological forethought and purpose as would be acceptable in a study of hu-

dogs, should occasionally reach the tissues of children. In one instance a larva in a child's liver has been questionably identified as *T. cati* (14).

Greatest anticipation of early incrimination is with *Ancylostoma caninum*. This worm is more common in dogs than *T. canis*, and occurs in cats as well as dogs. Whereas *T. canis* is relatively uncommon in older dogs and is especially uncommon in sexually mature females, *A. caninum* is found in both dogs and cats at all ages. Both parasites take full advantage of prenatal infection in maintaining a high level of endemicity and both are known to persist in the tissue of experimental animals for more than a year. There is no apparent reason why the larvae of *A. caninum* should not be found in the tissues of children along with the *Toxocara* species. However, further studies may bring to light an explanation which is presently not apparent. Larvae entering the body through the skin are less apt to be found in the liver and it is probable that *A. caninum* larvae are much less frequently ingested than the eggs of *Toxocara* and some of the other helminths.

The searching of liver biopsies for *Toxocara* larvae has in recent years uncovered three cases of *Capillaria hepatica* which formerly was found only at autopsy and was thought to be rare in man. It is hoped that when nematode larvae are encountered in the examination of human tissues it will not be assumed on circumstantial evidence that they are any particular species but rather will be identified on the basis of characteristic morphology.

Third Step

The third notable contribution to our knowledge of larva migrans came from a series of studies on the basic life cycle patterns among the ascarids. Originally our domesticated dogs and cats

may have acquired their ascarid and perhaps some of their hookworm infections not directly from the soil but indirectly by eating other mammals which by feeding on the ground had earlier picked up the infective stages, preserved or further incubated them in their tissues, and passed them on to their predators.

Experimentally, *T. canis*, *T. cati*, and *A. caninum* can be transferred to their final host by first inoculating mice or other small mammals which are then after several days, weeks, or months fed to dogs or cats. The significance of such observations is immediately apparent. They point out that our previous interpretation of larva migrans caused by these species was essentially incorrect. The migration and persistence without development in human tissues are not, as we had supposed, basically due to an abnormal host relationship. We may still regard man as an abnormal host for the adult stage, and an unnatural host for the larvae in that he provides no advantage for the parasite as a species, but the behavior of the larvae in man being the same as in natural transport hosts apparently is not abnormal. It is then to be expected that any of the larval stages of nematode parasites of wild or domesticated carnivorous animals adapted to the use of mammalian intermediate or transport hosts may grasp the opportunity to enter the tissues of human hosts and await, unsuccessfully of course, the transfer to a predator final host.

It is obvious from these remarks that detailed studies on the life cycles of all worm parasites of animals having contact with humans have great usefulness in the study of larva migrans and other zoonotic helminthiases.

Fourth Step

The fourth major advance in larva migrans research was Nichols' demonstration of the feasibility of identifying nematode larvae in microsections of tissues (16, 17). These classic morphological studies, while limited to only a half dozen species considered most likely to be encountered in human tissues, left no doubt that descriptions of these and other species could be sufficiently detailed to permit reliable identification often when only fragments of the larvae are available for study. The interpretation,

Considering the Aged

A. L. CHAPMAN, M.D.

MANY institutions and many programs are feeling the pinch of greater and greater demands on their facilities by older people. At the Peter Bent Brigham Hospital in Boston, for example, 7 percent of the patients during 1913-18 were 61 years of age or older as compared with 20 percent for the 1938-43 period. At present, the ratio is well above 20 percent and may approach 30 percent. Unpublished records from the Massachusetts General Hospital in Boston, as another example, show that the average age for all medical admissions, excluding pediatrics, rose from 35 years in 1912 to 60 years in 1949.

In the visiting nurse programs, too, the case-load has become increasingly weighted with older and chronically ill persons. Some estimate that approximately 50 percent of the visiting nurses' time is spent with these patients.

In a rehabilitation clinic for the crippled and handicapped, my final example, the ratio of approximately 5 children to 1 adult a few years ago is now nearly reversed.

It is not surprising, therefore, that anyone engaged in public health work or private medical care finds himself a practicing gerontologist. The public health practitioner, more than ever, must be prepared and willing to accept the new responsibilities imposed on him by an aging population and to find new ways of working with other professions concerned with the same problem.

Dr. Chapman, an Assistant Surgeon General, is chief of the Division of Special Health Services, Public Health Service. This article is based on a lecture given at the Summer Institute in Social Gerontology, held at the University of Connecticut in Storrs, August 28, 1953.

The seeds of chronic illness are planted early in life, perhaps before birth, necessitating a continuum of services throughout life, from infancy on, and not abruptly at the onset of old age, when chronic illness is most prevalent. The multiplicity of services and organized community efforts required by patients with chronic illness makes the health of older people everybody's business. To provide effective community response to the increased importance of socioeconomic factors, the resources of many agencies and people need to be pooled. Of course, the demands of the chronically ill and aged are in competition with other insistent matters such as radiological health, air pollution control, accident prevention, and the traditional concerns of the community. Thus, consideration of the older person's needs must be balanced with the needs of all members of the community, regardless of age or status.

Control of Chronic Disease

Many public health officials prefer the term "control" to "prevention" when speaking of chronic disease, primarily because of the broader implications of control. Control of chronic disease has been described as the maximum application of existing knowledge and resources to reduce the impact of chronic disease on the individual, his family, and society.

This concept may be considered in the light of five levels of control proposed by Dr. Hugh R. Leavell and Dr. E. Gurney Clark: health promotion, specific protection (primary prevention), early recognition and prompt treatment (secondary prevention), limiting the extent of disability, and rehabilitation.

Obviously, a community program meeting all these needs is an idealistic goal, but a synthesis

man disease. In fact such studies can be regarded as being directly concerned with human disease. We are only beginning to appreciate the importance of including household pets in the total picture of the family's and the public's health.

Second National Conference on World Health

The Second National Conference on World Health will be held in Washington, D.C., May 7-9, 1959, under the sponsorship of the National Citizens Committee for the World Health Organization. Conference chairman will be Dr. Milton S. Eisenhower, president of the Johns Hopkins University. Topics include prospects for the International Health Year; health and population changes; health and the American image abroad; and training and exchange programs for public health personnel.

cern to public health workers: (a) the personality of the older person, (b) his social and cultural background, (c) his economic status and ability to pay for services, (d) the attitude and orientation of the community, its leaders, and professional groups, and (e) the availability of community resources and services.

As people age, they become less and less like other people of the same age. They become individualists, and treating them as a homogeneous group becomes more and more difficult. Any health program that depends on a mass approach must take account of this fact. Older people have participated only to a limited extent in community X-ray surveys, multiple screening clinics, and mass immunization programs for poliomyelitis. Even when specialized geriatric programs have been established in hospital outpatient departments, the response has not been enthusiastic. It is as if the older person views these events as further attempts to isolate him, and the belief outweighs the advantages he may see in preferred treatment.

Social isolation of many aging people is a factor closely related to their failure to participate in community programs. The loss of job, spouse, family, and friends, and the gradual restriction of social activities may very well mean infrequent and brief contact with those who remain.

Education aimed at social or cultural groups in schools, industry, service organizations, or elsewhere will not reach many of these people. In fact, the educational media of radio, television, newspapers, and other printed materials may also fail in their goals because of this isolation. How can health services and programs be "sold" to the individual whose main contact with the outside world is a monthly check from the Social Security Administration, an infrequent visit from a welfare worker, or an occasional, superficial exchange of conversation with local trades people?

Chronic illness and its restrictions upon activity add to social attrition and accentuate, furthermore, the defeatist attitude of the older person and of society as a whole. The attitude of "why bother" when one is old, sick, and alone can lead to a failure of, or lack of interest in, rehabilitation activities for older people. Since the goals of rehabilitation for this group are,

for the most part, no more than self-care or activities of daily life, not full employment, the professional worker and older person may become disinterested and apathetic. Rehabilitation is hard work and the measurement of clear-cut results is often difficult.

Of importance, too, is the attitude of aging people toward preventive medicine. They have been reluctant to participate, as mentioned before, in many different kinds of preventive programs. Surely, their attitude is more than simply not wanting to bother; the feeling may spring from deep rooted fears of not wanting to borrow trouble: "What I don't know won't hurt me." Then, too, the past and present are more important to the older person than the future, so that health measures taken today for the future prevention of disease and disability have little meaning to him.

Prepaid health insurance plans for this age group may be the best solution, but the task of "selling" such plans is an additional burden.

Care for the Older Person

The emphasis on youth and work in America undoubtedly has had a bearing not only on the pattern with which health services have developed but, as has been indicated, on the use of these services as well. In addition, industrialization, a mobile population, and the dwindling size of families and of living accommodations have created a demand for new services and programs for older people and yet at the same time have proved a deterrent to these services.

To illustrate the increasing demands for specialized services, let us consider the phenomenal growth of nursing homes in the past decade or so. At present, an estimated 300,000 aged persons are being cared for in some 25,000 nursing homes and related facilities, where, for the chronically ill, nursing care is the predominant need. The demand for such institutional care is still growing, but many older people still remain in general and special hospitals, particularly mental institutions; adequate nursing homes cannot be found for them.

It is obviously a problem with both qualitative and quantitative aspects. Qualitative control of nursing homes by licensure, inspection, and establishing standards has become predominantly a public health function. A tre-

of services at each level would produce a comprehensive program. As the center core of health and medical services for the older person develops, other agencies and personnel will be found contiguous to the core and influencing the health of the individual. Basic planning for health must include, therefore, cooperative action in housing, employment, recreation, and education.

What are the activities which might be performed on each of the five levels of chronic disease control?

Health Promotion

Health promotion encompasses all educational activities which teach people how to maintain and improve their health. For the health agency, this means providing information on diet, rest, recreation, sound personal habits, and the availability of community resources in times of health and illness.

In promoting health, of greatest importance is the need to eliminate prejudices that are all too prevalent among the families of older people, professional groups, and among older people themselves.

Specific Protection

Primary prevention is more commonly practiced in communicable disease, the occurrence of which may be averted through immunization or isolation, than in chronic disease, knowledge about which is insufficient to permit specific protection except in certain instances. Among these instances, one may point out the possibility of industry's preventing occupational cancer through the removal of carcinogenic substances in the environment and the possibility of preventing accidents, particularly in the older age group and in the home, by a variety of measures. If the relationship is firmly established between smoking and lung cancer and between fats and cholesterol in the etiology of atherosclerosis, then specific protection may be equally applicable here.

Secondary Prevention

Of utmost importance at present for the control of chronic disease is the detection of a disease in an early stage and prompt treatment to check its progress and to retard any ensuing disability.

Widespread secondary prevention of chronic disease has been witnessed in the past few years. Single and multiple mass screening programs and periodic health appraisals in the offices of physicians, in hospitals, and in industrial clinics have given promise of providing an important wedge in the control of chronic disease.

Based on the concept of the well child conference, which places children under medical supervision while they are still well, a new development in geriatrics is taking hold. This is the well oldsters conference to which apparently well older people may come for counseling, guidance, health appraisal, and referral to medical care services when necessary.

Limiting Disability

When a disease is clinically advanced or is incurable, other measures must be taken. The services for the aged or chronically ill which attempt to limit the extent of disability cover a broad spectrum of medical and nursing care. To meet the ideal of comprehensive care, the patient would be cared for in his home, in outpatient clinics, physicians' offices, general and special hospitals, nursing homes, and homes for the aged.

Rehabilitation

Services to restore an individual's physical, mental, social, and vocational state as completely as possible may be found in such diverse places as a nursing home, hospital, or large metropolitan rehabilitation center. Many kinds of services are offered, such as physical and occupational therapy, medical and nursing care, and the adjuncts of vocational guidance and counseling, social service, and sheltered or homebound work opportunities. Thus, at the level of rehabilitation, perhaps more than at any of the other four levels, the active participation of a multidiscipline team is essential to effective operation.

Deterrents to Programing

For the most part, the deterrents to a community health program for the chronically ill and aged are socioeconomic, and may appear among any of the following, which are of con-

clinical and pathological aspects of aging. Public health workers who would help these people conserve their health cannot, therefore, ignore the older person's requirements in food, clothing, and shelter. Nor can public health workers ignore the interdependence of health and leisure, employment, and social relationships. It follows, therefore, that to obtain optimum adult hygiene, the disciplines of medicine, public health, and the social sciences must be called on for help.

Training and Education

The fact that public health workers have, without any directed change of policy, found themselves working with older people entails training the health specialist so that he may have the necessary knowledge and skill to perform his new responsibilities capably.

Training in chronic disease and aging is needed at two levels: formal, long-term courses for professional workers prior to their entrance into public health, and short-term refresher or "re-tread" courses for those already in the field.

A recent study of the curriculum of schools of public health revealed that a surprising amount of time (indeed, a continually increasing amount of time) was spent in lectures, seminars, field visits, and student assignments on chronic disease and aging. Professional training is exposing public health workers to basic concepts and problems relating to the chronically ill and aged person.

Short-term training is gaining momentum, also. Large numbers of professional, semi-professional, and lay persons have availed

themselves of refresher courses, seminars, institutes, inservice training courses, and the like. These activities have brought to the participants new skills and knowledge, but more important they have stimulated interest and provided an impetus to community programming.

Need for Research

In describing the impact of aging on health programs, I have hopefully indicated, perhaps indirectly, where gaps exist. The social scientist may help fill in these gaps through research. Health workers, in order to develop sounder programs for the older person, need more information on (a) the attitudes of the community, professional workers, and the elderly on aging and programs for aging persons, (b) the reasons behind the use or nonuse of community health facilities, (c) the relationship of health and illness to work, leisure time activities, and attitudes toward others, (d) the important factors that motivate older persons to seek rehabilitation, and (e) the barriers and incentives to good community planning.

Changes have taken place that necessitate a fresh approach to the solution of the ever-increasing problem of an aging population. We in public health feel that this is one of the most important tasks confronting us today. Experimentation with new techniques and the application of present knowledge are not enough. Our ultimate goal cannot be reached without the strength and support of further research. And that goal will be reached when, through comprehensive community planning, we succeed in enriching the later years as we have extended them.

mendous task remains to be done to provide an adequate number of good nursing homes, well equipped and fully staffed with competent help. Licensure is not enough. Steps must also be taken to recruit and train nursing home personnel and to educate the community with regard to these needs.

The solution of the nursing home problem will not end the struggle of caring for the chronically ill and aged person. As a matter of fact, some 80 percent of the more than 2 million aged who were disabled for 3 months or more last year were cared for in their own homes. For those older persons living with spouse or relatives or with adequate resources for supervision, care in the home may not have been too difficult. But for the large numbers of older men and women living alone in inadequate quarters and with no one to assist them, home care is impractical however desirable. Organized home care programs are finding that these individuals need more than the medical and nursing care that they get in the home; they need homemaker or housekeeping services as well.

Homemaker services originated as a stopgap measure to prevent the dissolution of a family by providing a substitute parent during periods of disaster and stress. Like so many other programs, it was thus directed primarily toward children and their care.

In the past few years, however, there is increased awareness that other persons, primarily the chronically ill and older person, need these services. Some homemaker programs are attempting to meet these needs, but demand exceeds present capacities.

The goal of caring for the older person in his own home is obviously not easily achieved. The growth of home care and homemaker services is an essential part of the comprehensive program of care, but other means must be sought, such as foster home placement or the development of new facilities for graduated and selective care tailored to the immediate needs of each patient.

The Public Health Service is currently studying such a facility at the Manchester Memorial Hospital in Connecticut, which is providing care: (a) for the critically ill patient, (b) for those not dangerously ill, and

(c) for those who are ambulatory and capable of self-care. An adjoining unit provides long-term care, and home care has also begun.

Another step toward better care of the homebound patient, in this instance the stroke victim, has recently been taken by the Public Health Service. Many patients who have suffered strokes may either never be admitted to a hospital for care or, if they are, are discharged to a nursing home. Because members of the family are ignorant of how to prevent deformity and disability, they and professional personnel alike have watched helplessly as many victims of stroke have become permanently crippled and bedridden. Early ambulation of the stroke victim and active and passive exercises are means by which disability may be limited, and members of the family may aid the patient in these respects, thus saving the time of professional workers.

To aid in the limitation of disability, the Chronic Disease Program of the Public Health Service has prepared a booklet entitled "Strike Back at Stroke." Based on the family physician's prescription, it is an illustrated instruction manual for the stroke victim's family to assist them in his care.

Thus we find new programs developing as the result of socioeconomic changes, programs that are based on the premise that the most logical and acceptable place for the care of the older person is in his own home. In addition to those described above, there are other community programs such as "Meals on Wheels" (which has aptly been called the "Bicycle Built for Stew"), which serves hot, nutritious meals in the homes of older persons incapable of preparing their own meals.

Recent studies in urban communities have shown that homebound older patients would prefer assistance with simpler tasks, such as marketing and personal errands, or companionship, to meals served at home. The need for some degree of independence is still felt by older persons, regardless of the extent of their handicap or capabilities. The need for friendly visiting programs or housekeeping services therefore becomes more apparent.

Many activities, we see, not usually considered a part of public health are relevant to the health of older people and extend beyond the

In this country, most biological research is conducted in universities as an adjunct of teaching; the Soviets conduct most research in research institutions. Here, when an investigator assumes administrative or political duties, he usually discontinues scholarly research. In the Soviet research institutions, it is assumed that the administrative directors will continue their studies and that facilities will be provided to the extent they are available. For example, Pavlovsky, the father of Russian zoology, continues to publish reports of his new research although he has many official duties and is well advanced in years.

It is almost impossible for a Soviet scientist to comprehend the character of an American university or the procedures by which our research is financed. When I told my hosts that Tulane was a private institution, they assumed it was dedicated to profits, or that it returned a profit to the people who financed it, or that, since it was supported by gifts, it was a charity school for the poor.

Their ignorance of American institutions appeared to be a product of their specialized education, rather than a lack of curiosity or freedom of inquiry. So far as I could observe, they seemed relaxed in their attitudes and were willing to discuss any subject. Despite such events as Pasternak's refusal of the Nobel Prize, they appear to feel we exaggerate conditions there. Among the men I met was a geneticist who told me with some scorn that he was one of several reported by the American press as liquidated for opposition to Lysenko. During the period of his supposed suppression, he said he had published several major papers on genetics.

I was also assured repeatedly that Communist Party membership is not a factor in determining promotions in research institutes. A candidate, the term used for a predoctoral worker, is at first assigned duties according to the needs of his supervisors, but as he demonstrates a capacity for original investigation, he is given free rein and promotions according to the professional appraisal by his colleagues. On the other hand, on an occasion when I was admonishing my hosts that scientists must not behave like politicians, I was told that nearly

half of the scientists in the immediate gathering were members of the Communist Party. "We are not like politicians," my informant emphasized. "We are politicians."

Opportunities for Research

Research academies of the constituent Republics of the Soviet Union appear to be free to develop their own programs. They are not subordinate to the All-Union Academy, but the work of all academies is coordinated by a separate council. I am under the impression that each Republic finances its own research institutes and that they are under no other restraint as to the direction of their activities.

The institutions were adequately but not elaborately equipped. One celebrated institution I visited at Irkutsk on Lake Baikal is housed in a small wooden structure, with cubbyholes for individual investigators. In construction at this station, however, is a collection of brick buildings, scheduled for completion next year, to house the International Limnological Institute. One of the buildings is a dormitory planned for the use of scientists from other lands. Directors of the institute said they would like to have Americans and others come to work there for 6-month terms.

Typically, it did not occur to the Soviet scientists that an American might find it difficult to raise the money for such a stay. They are not even aware that some Americans have found it difficult to travel as they wish in the U.S.S.R., although they do know and deeply resent restrictions that have been placed on Soviet visitors to the United States. Their resentment is the stronger because many wish to come here on scientific missions.

Conclusions

From my conversations and observations, it appears that if we continue to expand present programs to send well-informed scientists from the United States for consultation with their Soviet colleagues, they would certainly be effective in improving Soviet understanding and respect for this country. Moreover, since the Soviet scientist has a direct voice in government decisions, the influence of American visitors could come to be felt in the highest political circles. It is recognized that such visitors need

Scientific Exchange

FRED R. CAGLE, Ph.D.

Specific steps for strengthening American science in relation to science in the U.S.S.R. are advocated by Professor Fred Cagle, chairman of the department of zoology, Tulane University, after 40 days of consultations with scientists in research institutes in the Soviet Union. Cagle visited Soviet centers in behalf of the American Institute of Biological Sciences. The following text is based upon informal remarks by Cagle in Washington, D.C., December 17, 1958. A formal report of this mission was published in the Bulletin of the American Institute of Biological Sciences, January 1959, pp. 16-20.

AFTER intense preparations, I went to Russia confident that I knew a great deal about the country. I returned aware mainly of my vast ignorance. As a scientist, what I learned was gratifying. As an American, I also found it frightening.

Although in many respects Russian biological sciences are less advanced than ours, the rate of progress is such that in a few years ours can easily be surpassed.

Science Carries Weight

I was particularly impressed with the influence that scientists enjoy in their government. Many of them have a status and responsibility comparable to that of a Senator or Congressman in this country. One of the botanists I met impressed me particularly by the intelligence of her questions about America. For this reason, I inquired about her and learned that she was a deputy president of one chamber of the Supreme Soviet.

Scientists, I was told, do not merely advise or recommend but actually plan the studies which should be carried on in connection with such public projects as, say, a new reservoir. And in pursuing such studies, which aim primarily at practical applications, as does most Soviet

science, it appears that they also provide for basic research. Like us, Soviet scientists wish to answer fundamental questions as well as the immediate ones.

Eager to Exchange

Soviet scientists are eager for us to know what they are doing. Repeatedly they expressed irritation to me because we do not read their literature. Although they do not understand why we do not learn Russian, they have published many of their papers with both Russian and English titles and with abstracts or summaries in English. With some encouragement from us, they would certainly do more to make their papers available in English.

They tend to publish their more valuable papers as monographs, for which they are well paid, rather than in serial journals. So it becomes necessary for us to learn not only what is available in their literature but also how to appraise it. Several scientists expressed amazement that we had bothered to translate some of the Russian works which we have put into English, and on the other hand they could not understand why we had ignored certain important biological studies.

Ignorance of America

Learned though they are in their sciences, the Soviet scholars are remarkably ill-informed about American scientific institutions and their operations. To illustrate the contrasting customs: When an American requests a Russian publication from a Soviet scientist, the book is procured and mailed at government expense; but when a Russian puts such a request to an American university professor, the book is sent as a courtesy, often at considerable personal expense.

In this country, most biological research is conducted in universities as an adjunct of teaching; the Soviets conduct most research in research institutions. Here, when an investigator assumes administrative or political duties, he usually discontinues scholarly research. In the Soviet research institutions, it is assumed that the administrative directors will continue their studies and that facilities will be provided to the extent they are available. For example, Pavlovsky, the father of Russian zoology, continues to publish reports of his new research although he has many official duties and is well advanced in years.

It is almost impossible for a Soviet scientist to comprehend the character of an American university or the procedures by which our research is financed. When I told my hosts that Tulane was a private institution, they assumed it was dedicated to profits, or that it returned a profit to the people who financed it, or that, since it was supported by gifts, it was a charity school for the poor.

Their ignorance of American institutions appeared to be a product of their specialized education, rather than a lack of curiosity or freedom of inquiry. So far as I could observe, they seemed relaxed in their attitudes and were willing to discuss any subject. Despite such events as Pasternak's refusal of the Nobel Prize, they appear to feel we exaggerate conditions there. Among the men I met was a geneticist who told me with some scorn that he was one of several reported by the American press as liquidated for opposition to Lysenko. During the period of his supposed suppression, he said he had published several major papers on genetics.

I was also assured repeatedly that Communist Party membership is not a factor in determining promotions in research institutes. A candidate, the term used for a predoctoral worker, is at first assigned duties according to the needs of his supervisors, but as he demonstrates a capacity for original investigation, he is given free rein and promotions according to the professional appraisal by his colleagues. On the other hand, on an occasion when I was admonishing my hosts that scientists must not behave like politicians. I was told that nearly

half of the scientists in the immediate gathering were members of the Communist Party. "We are not like politicians," my informant emphasized. "We are politicians."

Opportunities for Research

Research academies of the constituent Republics of the Soviet Union appear to be free to develop their own programs. They are not subordinate to the All-Union Academy, but the work of all academies is coordinated by a separate council. I am under the impression that each Republic finances its own research institutes and that they are under no other restraint as to the direction of their activities.

The institutions were adequately but not elaborately equipped. One celebrated institution I visited at Irkutsk on Lake Baikal is housed in a small wooden structure, with cubbyholes for individual investigators. In construction at this station, however, is a collection of brick buildings, scheduled for completion next year, to house the International Limnological Institute. One of the buildings is a dormitory planned for the use of scientists from other lands. Directors of the institute said they would like to have Americans and others come to work there for 6-month terms.

Typically, it did not occur to the Soviet scientists that an American might find it difficult to raise the money for such a stay. They are not even aware that some Americans have found it difficult to travel as they wish in the U.S.S.R., although they do know and deeply resent restrictions that have been placed on Soviet visitors to the United States. Their resentment is the stronger because many wish to come here on scientific missions.

Conclusions

From my conversations and observations, it appears that if we continue to expand present programs to send well-informed scientists from the United States for consultation with their Soviet colleagues, they would certainly be effective in improving Soviet understanding and respect for this country. Moreover, since the Soviet scientist has a direct voice in government decisions, the influence of American visitors could come to be felt in the highest political circles. It is recognized that such visitors need

to be well informed, and should be well briefed in advance. I found also it was quite helpful to have personal letters of introduction wherever I visited. As many Russians speak English, the language barrier is not overwhelming, but it is nevertheless an incalculable asset for the visitor to know the language of the host country, if only as a matter of good will.

Another means we may use to inform Soviet scientists about the United States is to publish, in our scientific journals, essays which comment upon and explain some of the complexities of our society. We can also expand our exchange of journals. The scientific libraries of the various Republics are usually inadequate and they would like to exchange with us. It would not

be difficult to prepare a list of libraries which wish to share in such an exchange.

To encourage the publication in English of abstracts of Russian papers, we might reciprocate by publishing Russian language abstracts of important American contributions. We also need to make a more systematic effort to study, appraise, and collect Russian biological literature, as a phase of the current Russian translation program.

In my judgment, we should send more biologists to work in the U.S.S.R. At present there is only one biologist on the staff of our Embassy in Moscow. Strong representation there, I feel, could do much to inform Soviet scientists about American scientists and their work

Results of a Survey on Hearing Loss in Children

Only 15 to 20 percent of the school children with known hearing losses are receiving any kind of educational help, according to the findings of the Committee for Hearing Conservation, American Public Health Association.

The committee, after 3½ years of study, conservatively estimates that 5 percent (1,790,176) of the total school population would fail group hearing tests, and, of these, 39 percent (698,168) would be expected to have true hearing losses.

The study, which was co-sponsored by the American School Health Association, covered 1,362 communities in 48 States. Of these communities, 39 administered only one test during the school life of their children, and 7 of these did not begin testing until the seventh grade. Another 15 communities, which gave two or three tests, also began testing in the seventh grade or later. Yet research clearly indicates that the best preventive work is done when hearing losses are detected early and referred for medical help. By the time a child reaches the seventh grade, hearing loss may

be irreversible. Furthermore, if irreversible cases are found early enough, proper education and treatment would promote better adjustment and learning.

The study also revealed that there is no uniform program in the United States for detecting hearing losses in school children. Some areas have a program that is considered very satisfactory, but others have no program at all.

Moreover, there is no uniformity in the criteria used in determining failure on any of the audiometric tests, in the administration of tests, in referral for treatment, in notifying parents, or in the kind of treatment and education given.

Dr. C. Adele Brown, chairman of the Committee for Hearing Conservation, and director of school health services, Oswego, N.Y., reported these findings. Other members of the committee were Dr. L. M. DiCarlo, Dr. I. P. Barrett, Dr. M. E. Doster, Dr. C. D. O'Connor, Dr. C. N. Brownsberger, Dr. A. Yankauer, and T. J. LePine.

Employees' Health Insurance Program of New York State

EDWARD D. MEACHAM, M.S.P.A.

IN 1955, Governor Averell Harriman requested the president of the New York State Civil Service Commission to survey the status of fringe benefits for State employees. The survey was made by the department of civil service and submitted to the State budget director in October 1955. Chief among the recommendations resulting from the survey was that the State should provide some kind of health insurance coverage for its employees. This recommendation was based in part on findings that State employees were generally less favorably treated in this area than were employees of industrial and commercial enterprises. Also, it was felt that this particular type of employee benefit would meet a real employee need and would benefit the State as well.

During the 1956 session of the State legislature, several bills proposed some kind of health insurance coverage for State employees. One of these bills was introduced at the request of the State administration. Another bill was introduced by a State senator whose Joint Legislative Committee on Health Insurance Plans had been studying the general subject of health insurance coverage for some time. Still other bills were introduced under other sponsorship.

What finally emerged was a bill to add article VII to the New York State Civil Service Law. This bill was signed into law by Governor Harriman as chapter 461 of the New York State Laws of 1956. It provided for the creation of a Temporary Health Insurance Board and au-

thorized the president of the New York State Civil Service Commission to "establish a health insurance plan for State officers and employees and their dependents" and "to purchase a contract or contracts to provide the benefits under the plan" The law stated the general character of the plan as follows:

The health insurance plan shall be designed by the president, with the approval of the board, (a) to provide a reasonable relationship between the hospital, surgical, and medical benefits to be included, and the expected distribution of expenses of each such type to be incurred by the covered employees and dependents, and (b) to include reasonable controls, which may include deductible and reinsurance provisions applicable to some or all of the benefits, to reduce unnecessary utilization of the various hospital, surgical, and medical services to be provided and to provide reasonable assurance of stability in future years of the plan, and (c) to provide benefits on a nondiscriminatory basis to the extent possible to active members throughout the State, wherever located.

The statute prohibited coverage of certain kinds of expenses and placed a limit on the State contribution toward the cost of the insurance. Among the kinds of expenses excluded are expenses for dental care and treatment, eye glasses and hearing aids, cosmetic surgery, treatment for illness or injury arising out of employment and covered under workmen's compensation, services received in a United States Government hospital for which no charge is made, and expenses to the extent of benefits provided under any other employer group plan.

Mr. Meacham is director of personnel services, New York State Department of Civil Service.

The law also provided that coverage could be continued after an employee retires from State service. And it provided that any contracts purchased by the president of the civil service commission were to be subject to approval by the Temporary Health Insurance Board.

The Temporary Board

The Temporary Health Insurance Board, appointed pursuant to the provisions of the statute, consisted of four members appointed by the Governor, two members appointed by the temporary president of the senate, and two members by the speaker of the assembly. The board first met in June 1956.

Since the responsibility for the development of the program rested with the president of the civil service commission, staff work for the board was assigned to the personnel services division of the department of civil service.

While chapter 461 provided that the plan should be designed by the president of the civil service commission, it was his opinion that the board should cooperate in its development in order to expedite approval. The board agreed that it should develop its own specifications rather than purchase an existing "package" plan from a carrier.

Members of the staff submitted to the board comparative information on benefits under several large plans. The staff also submitted a statement of a comprehensive plan for board discussion. Since the board could not agree on this type of program, it was decided to set forth in detail the kinds of benefits which could be agreed to as essential to any well-rounded health insurance program. The descriptions of these various benefits became the preliminary specifications which were ultimately submitted to several carriers.

At this time it became evident that it would be desirable to have the advice and assistance of technically qualified personnel from the various carriers. A Technical Advisory Committee consisting of representatives of the Blue Cross and Blue Shield plans in New York State and of the insurance industry was appointed. During the course of the early deliberations of the board and the Technical Advisory Com-

mittee, the opinions of several employee groups were obtained.

To aid the board in estimating the probable cost of the program, the members of the Technical Advisory Committee submitted estimates of costs on a unit basis for each of the benefits under consideration. (One set of estimates was submitted by representatives of Blue Cross-Blue Shield and a separate set by representatives of the commercial insurance companies.) With this information, the board was able to discuss more realistically the kind of program it could construct within the fiscal limitations established by law and by State fiscal authorities.

Characteristics and Specifications

While information on the benefit program was being developed, the staff compiled data on group characteristics which would be essential if the proposals of the carriers were to be realistic. Information was included on the age distribution of State employees, the number of male and female employees, the salary distribution for these employees, the age, number, and sex of retired employees, the number of employees living in the various geographic areas of the State, and other related information.

In connection with this phase of the program, the State health department, in cooperation with the staff of the department of civil service, surveyed by questionnaire some 3,000 State employees to determine the extent of their present health insurance coverage and to learn their desires as to the kind of program they felt the State should adopt. The department of audit and control, through the New York State Employees' Retirement System, also made available a considerable amount of information with respect to the coverage group.

To maintain flexibility with respect to adoption of the final plan, the board agreed that the specifications should include eight alternatives in addition to the basic specification. These alternatives had to do with immediate coverage of maternity care, physicians' attendance in the hospital, use of an initial amount of payment (deductible) in connection with basic hospital, basic surgical, and in-hospital coverage, private duty nursing service, amount of obstetrical indemnity, and conversion privilege.

These specifications were approved by the board early in 1957, and the following few weeks were spent in developing forms and other materials to be sent to carriers with invitations to submit proposals. Although the board was not required, under chapter 461 of the New York State Laws of 1956, to get competitive bids, nevertheless it was deemed desirable to obtain proposals from as many different carriers as cared to submit them. Invitations were sent to approximately 50 insurance companies and nonprofit medical or hospital service corporations. The materials included with the invitation were:

1. The description of benefits.
2. A statewide fee schedule for surgery, radiation therapy, and physicians' attendance in the hospital for medical care. (The statewide schedule was essentially the same as that used in the Medicare program in New York State.)
3. An area fee schedule for surgery, radiation therapy, and in-hospital medical care. (The area fee schedules used were those of the Blue Shield plans operating in New York State.)
4. A schedule for obstetrical services.
5. State employee population characteristics.
6. Distribution of State employees by age and sex.
7. Distribution of State employees by salary levels.
8. Distribution of State employees by county of residence.
9. Distribution of retired State employees by age.
10. Instructions for submitting premium or subscription charges.
11. A list of eight questions relating to conditions applicable to providing services and benefits.
12. Forms to be used in submitting proposals and in estimating costs and retentions for a 10-year period.

The carriers were asked in submitting their proposals to show separate figures for active employees and for "future retired" employees. In each case, they were asked to show separate figures for part I, hospitalization benefits, part II, basic surgical, radiation therapy, and in-hospital benefits, and part III, major medical expense benefits. They were also asked to show a composite cost per employee based on a distribu-

tion of 35 percent individual coverage and 65 percent individual and dependent (family) coverage. The carriers were requested to show the total first-year premium cost for 70,000 active employees and 450 retired employees. They were requested also to show a separate figure for maternity costs if no waiting period was imposed for the charter group. Finally, the carriers were requested to show a 10th-year premium, again based on 70,000 active employees, but with 7,200 retired employees to be covered during the 10th year. (It was recognized that the figure, 70,000 actives, for the 10th year was not realistic since it did not anticipate any increase in the size of the employee group. It did illustrate the effect of expected higher costs as more employees reached retirement age.)

In estimating retentions, the carriers were requested to show for each of the first 10 years the premium or subscription charge, rate credits, dividend or retroactive credits, net costs, incurred claims, and total returns and retentions, including taxes, expenses, and reserves. Retentions were to be based on an assumption of incurred claims of 85 percent under part I, 85 percent under part II, and 75 percent under part III, and also for incurred claims of 75 percent on part I, 75 percent on part II, and 70 percent on part III.

Proposals of Carriers

The specifications were mailed on February 28, 1957, and the carriers were asked to return their proposals to the department of civil service not later than March 29. Representatives of the carriers were invited to be present when the proposals were opened.

Eleven carriers submitted proposals on one or more parts of the program. At this point, it was determined that the department of civil service should have the assistance of consultants in the insurance field to help analyze the proposals. The chief actuary of the Insurance Department of New York State prepared an analysis and report, including recommendations, on the proposals. The department also obtained the services of an insurance consultant who also analyzed the proposals and submitted a report to the president of the civil service commission.

Representatives of the staff, together with the consultants, then met informally with representatives of six of the carriers whose proposals were deemed best. At these conferences, the carriers' representatives were asked to explain in greater detail various aspects of their proposals and were questioned by the consultants and by staff members. Subsequently, the reports were turned over to the Temporary Health Insurance Board. The six carriers were given the opportunity to appear before the board to describe and support further their respective proposals. Members of the board were given the opportunity to question each of the carriers' representatives.

Following the presentations by the carriers' representatives, the board, with the two consultants present, discussed the proposals. After lengthy deliberation, the board decided to negotiate with the Blue Cross corporations of New York State for the part I hospitalization benefits, with the Blue Shield corporations of New York State for the part II surgical, radiation therapy, and in-hospital benefits, and with the Metropolitan Life Insurance Company for the part III major medical expense insurance benefits.

The contracts with these carriers were to constitute what subsequently became the "statewide plan" for which all State employees were eligible. The board also approved two optional plans, both of which carried the basic hospitalization coverage provided through the Blue Cross plans of New York State, but which in other respects differed from the statewide plan. One of these options was the Group Health Insurance, Inc., and the other, the Health Insurance Plan of Greater New York.

The board approved the program in June 1957, and the contracts providing for coverage were completed in August.

Enrollment

At this point, so as to inform prospective enrollees, it became necessary to fix a date on which coverage was to begin. This date had to be fixed sufficiently far in advance to permit the preparation of literature and the organization and the carrying out of an adequate educational and enrollment campaign.

The development of the necessary descriptive literature was a difficult task. In any program in which there is more than one carrier, care must be exercised to insure that the plan is described accurately and fairly, especially if employees are to have options. Two different booklets and two different enrollment forms were issued to prevent confusing the employees unnecessarily. One booklet described the statewide plan and the two options; the other described only the statewide plan, since this booklet was to be used in those areas where only the statewide plan would be available.

Enrollment of not less than 75 percent of the eligible employees was required under the terms of the contracts. It was estimated that, to achieve this percentage, 3 to 4 weeks of intensive enrollment would be required. Basically, the educational program was decentralized to the various departments and agencies of the State government. In order to do this, it was necessary to hold intensive training sessions for those who would conduct the employee meetings. The first session was of 3 days' duration and was limited to training personnel who were well acquainted with the techniques of presenting material to groups of employees. This group needed only to be instructed in the details of the health insurance program. The other sessions lasted 5 days and included not only details of the program but also techniques of presentation. Each department or agency sent one or more representatives to a training session; these trained individuals then returned to the agency to conduct employee meetings.

In the department of mental hygiene, with its 25 institutions and some 30,000 employees, the presentations were made by staff members of the health insurance unit in the department of civil service. Booklets and enrollment forms were distributed by the agencies, and educational material was made available through the employees' press and through the *State Personnel News*, a publication of the department of civil service which reaches all employees.

The fact that a number of employees working in State hospitals receive a considerable amount of medical care without charge tended to affect enrollment adversely. Also many State employees already had coverage through a spouse who worked in an industrial or commercial

establishment. The effectiveness of the enrollment program, however, was attested to by an original enrollment of more than 73,000 employees, which was in excess of the 75 percent required.

The plan went into effect on December 5, 1957. During the first 6 months, more than 25,000 claims were presented. It has not been possible as yet to analyze these claims in detail to determine incidence of various types of illnesses, number of hospital admissions, average length of hospital stay, and other similar information. The claim figures cited above do not include claims under the GHI option nor do they cover services under the HIP option.

Summary of Benefits

While it is not appropriate here to describe in detail the plans, a summary of the benefits will provide a general understanding of the program.

The statewide plan consists of the three parts mentioned previously. Hospitalization benefits are provided under part I. Benefits for surgery, radiation therapy, anesthesiology, obstetrics, and in-hospital medical care are provided under part II. Part III covers major medical expense benefits, including a wide range of medical care expenses divided generally into (a) extensions of the benefits provided under parts I and II and (b) benefits for certain services not covered under parts I and II.

The statewide plan and the two options provide the same basic hospitalization benefits, which include:

1. A total of 120 days' room and board charges at the semiprivate accommodation rate. (If a private room is occupied, the benefit allowed equals the charge most common for a semiprivate room.)

2. All hospital diagnostic and therapeutic services.

3. Maternity benefits of flat amounts.

4. Emergency outpatient services for treatment of injuries arising from accidents or for emergency surgery if given not later than the day following the accident.

The contract provides for hospitalization benefits for pulmonary tuberculosis and for mental or nervous disorders, but the benefit in

such cases is limited to 30 days in a general or public hospital rather than 120 days.

Maternity care under part I and obstetrical benefits under part II total \$150 for normal delivery, \$175 for cesarian section or ectopic pregnancy, and \$50 for a miscarriage. In the \$150 indemnity for a normal delivery, \$75 is paid through Blue Cross under part I, and \$75 through Blue Shield under part II (or \$87.50 each for cesarian section and ectopic pregnancy, and \$25 each for a miscarriage). If, in a normal delivery, the amount under part I should be only \$60, then Blue Shield could pay the difference between this amount and \$150, or \$90. The same relationship exists between benefits under part I and part II in the payments for cesarian section and miscarriage.

The part II benefits, as well as the benefits under part I, may be extended by the major medical expense portion of the program, part III. If, for example, the benefits for surgery under part II fail to meet the entire cost, the excess cost is subject to reimbursement under part III. An illustration of how part III extends the benefits of part I is the case of the person who stays in the hospital for more than 120 days. Under the major medical expense program, benefits are provided for these additional days. In addition, part III of the program covers such services as private duty nursing, drugs and pharmaceuticals, rental of durable equipment, prosthetic appliances, and local professional ambulance services. These latter services are generally not covered under part I or part II of the statewide plan.

Benefits under part III are subject to an initial charge, or "deductible," of \$50 for each covered individual in each calendar year. Total benefits under parts I, II, and III of the statewide plan are limited to \$7,500 in any one year and \$15,000 in a lifetime, with reinstatement permitted under certain conditions after benefits of \$1,000 have been paid.

The GHI option covers general medical care, care of allergies, surgery, consultations, in-hospital medical care, maternity care, diagnostic laboratory procedures and diagnostic X-rays, and visiting nurse service.

The HIP option provides for general, medical, surgical, and obstetrical care, laboratory and diagnostic procedures, periodic health ex-

Representatives of the staff, together with the consultants, then met informally with representatives of six of the carriers whose proposals were deemed best. At these conferences, the carriers' representatives were asked to explain in greater detail various aspects of their proposals and were questioned by the consultants and by staff members. Subsequently, the reports were turned over to the Temporary Health Insurance Board. The six carriers were given the opportunity to appear before the board to describe and support further their respective proposals. Members of the board were given the opportunity to question each of the carriers' representatives.

Following the presentations by the carriers' representatives, the board, with the two consultants present, discussed the proposals. After lengthy deliberation, the board decided to negotiate with the Blue Cross corporations of New York State for the part I hospitalization benefits, with the Blue Shield corporations of New York State for the part II surgical, radiation therapy, and in-hospital benefits, and with the Metropolitan Life Insurance Company for the part III major medical expense insurance benefits.

The contracts with these carriers were to constitute what subsequently became the "statewide plan" for which all State employees were eligible. The board also approved two optional plans, both of which carried the basic hospitalization coverage provided through the Blue Cross plans of New York State, but which in other respects differed from the statewide plan. One of these options was the Group Health Insurance, Inc., and the other, the Health Insurance Plan of Greater New York.

The board approved the program in June 1957, and the contracts providing for coverage were completed in August.

Enrollment

At this point, so as to inform prospective enrollees, it became necessary to fix a date on which coverage was to begin. This date had to be fixed sufficiently far in advance to permit the preparation of literature and the organization and the carrying out of an adequate educational and enrollment campaign.

The development of the necessary descriptive literature was a difficult task. In any program in which there is more than one carrier, care must be exercised to insure that the plan is described accurately and fairly, especially if employees are to have options. Two different booklets and two different enrollment forms were issued to prevent confusing the employees unnecessarily. One booklet described the statewide plan and the two options; the other described only the statewide plan, since this booklet was to be used in those areas where only the statewide plan would be available.

Enrollment of not less than 75 percent of the eligible employees was required under the terms of the contracts. It was estimated that, to achieve this percentage, 3 to 4 weeks of intensive enrollment would be required. Basically, the educational program was decentralized to the various departments and agencies of the State government. In order to do this, it was necessary to hold intensive training sessions for those who would conduct the employee meetings. The first session was of 3 days' duration and was limited to training personnel who were well acquainted with the techniques of presenting material to groups of employees. This group needed only to be instructed in the details of the health insurance program. The other sessions lasted 5 days and included not only details of the program but also techniques of presentation. Each department or agency sent one or more representatives to a training session; these trained individuals then returned to the agency to conduct employee meetings.

In the department of mental hygiene, with its 25 institutions and some 30,000 employees, the presentations were made by staff members of the health insurance unit in the department of civil service. Booklets and enrollment forms were distributed by the agencies, and educational material was made available through the employees' press and through the *State Personnel News*, a publication of the department of civil service which reaches all employees.

The fact that a number of employees working in State hospitals receive a considerable amount of medical care without charge tended to affect enrollment adversely. Also many State employees already had coverage through a spouse who worked in an industrial or commercial

participate in the program. Under this change (chapter 950 of the Laws of 1958) there are several specific requirements for participation. The local subdivision must elect to participate, and its participation must be approved by the Temporary Health Insurance Board. It must pay the same rate of contribution as is paid by the State. The local subdivision is also required to pay its proportionate share of expenses of administering the plan as determined by the board. Finally, the local subdivision must agree to make its employment and payroll records available for inspection by the board.

In the present program approximately 88,000 employees are covered. With their dependents, the number covered is in excess of 200,000. If the total potential of the local subdivisions is realized, there would be an employee group of approximately 300,000 and a total coverage group of 850,000 to 900,000 persons. In addition, the present 12 employer participants would increase to more than 5,000. It is not anticipated, however, that all local subdivisions will participate, or that all of the employees in those subdivisions which do participate will enroll in the plan. Nevertheless, the coverage group will be one of the largest covered by a single set of contracts.

Before concluding, a word about administration is appropriate. The central administration of the health insurance program is the responsibility of the department of civil service. The health insurance unit of this department generally performs the following functions: maintains records of enrollment and status, certifies eligibility for benefits, interprets contracts when carrier disagrees, receives

money and pays premiums to the carriers, and evaluates the program. The State's departments and agencies enroll employees in the plan and aid employees in filing claims. They also make the necessary employer certification with respect to workmen's compensation cases.

Benefits provided through the Blue Cross plans and through the Blue Shield plans do not require submission by the employee of a claim form. This is true also of benefits provided under the HIP option. Claims for benefits under the major medical expense portion of the statewide plan are prepared by the employee and submitted to the Metropolitan Life Insurance Company through the personnel office in his agency. The claim form is accompanied by a worksheet also prepared by the employee. This worksheet itemizes expenses and includes space for the employee to indicate the total amount of benefits claimed. The employee may obtain assistance from his personnel office in preparing the worksheet if he wishes to do so. The claim form and worksheet are reviewed by the carrier and a check in the proper amount is sent to the employee through his agency's personnel office.

Under the GHI option, the employee has the doctor complete the appropriate section of the form. Then the employee completes the subscriber's portion and forwards it directly to Group Health Insurance, Inc.

Although there have been many administrative and other problems in connection with the program during the early months of its operation, there is widespread agreement that the plan is doing a good job for the employees at a reasonable cost to them and to the State.

Nuclear Medicine

A unit to study long-range effects of nuclear energy on public health has been established at the University of Chicago School of Medicine, supported in part by the Rockefeller Foundation.

The section on nuclear medicine will explore such matters as the increase in sources of public exposure to radiation, the consequences of increased exposure, control of factors responsible, medicolegal aspects of injury and compensation, and psychological reactions of society to threatening aspects of nuclear energy.

aminations and immunizations, physical therapy, visiting nurse service, and ambulance service.

The statewide plan is available to all State employees regardless of where they work or live. The GHI option is available in the counties of Albany, Bronx, Columbia, Delaware, Dutchess, Greene, Kings, Nassau, New York, Orange, Putnam, Queens, Rensselaer, Richmond, Rockland, Suffolk, Ulster, and Westchester. The HIP option is available only to those in the Bronx, Columbia, Kings, Nassau, New York, Queens, Richmond, Suffolk, and Westchester. (In Columbia, Nassau, Suffolk, and Westchester, the program is not available to all residents of the counties but only to those in areas served by the medical groups.)

Other Features of the Plan

Some other general features of the plan deserve mention. The employee may continue his coverage after he retires provided he has at least 5 years of State service and has participated in the plan the required length of time during his years of active service. The employee continues to pay his share of the cost of coverage after his retirement. Another feature is that benefits can be made available for services given either within or outside New York State.

We should also note the "service" feature of the plan which, under certain conditions, assures enrollees that the benefit will not be less than the charge made for the service. Under part II of the statewide plan, eligibility for "service benefits" depends on the employee's income status and his use of a participating physician. Under the GHI option, the employee must use a participating physician and, for covered services given in a hospital, must not apply for or use a private room if he is to be eligible for "service benefits." Under the HIP option, "service benefits" are available if the services are obtained from the medical group in which the employee participates.

Costs and Coverage

A word about costs. Under the statewide plan, the employee who buys coverage only for himself pays one-half of the cost and the State pays one-half. If he purchases coverage for

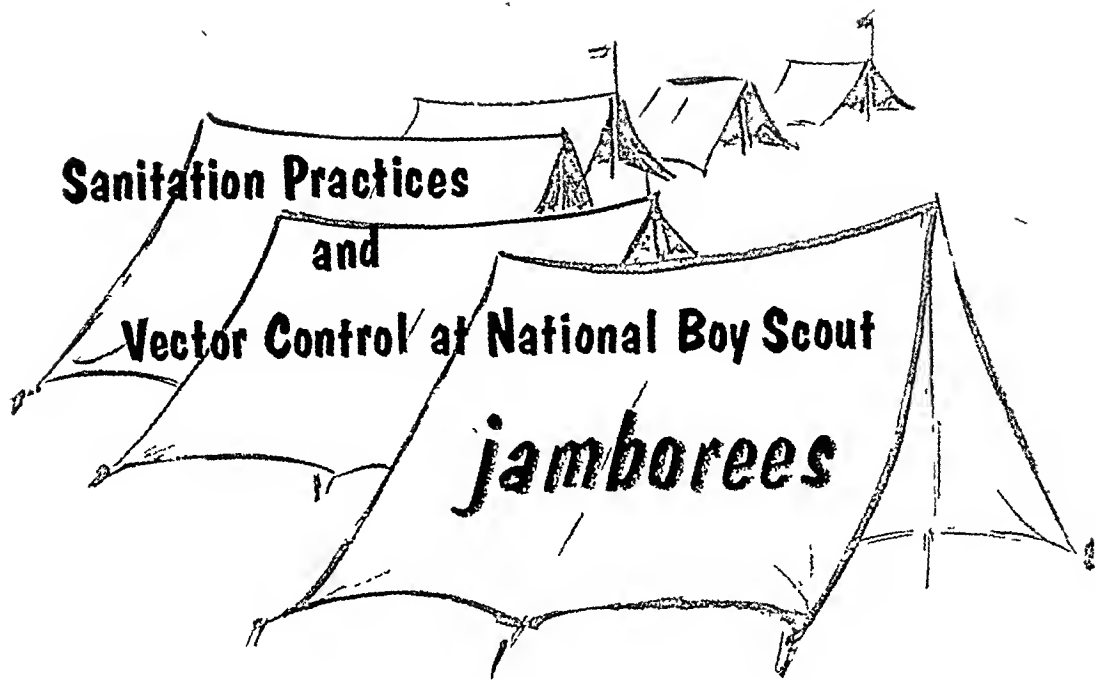

himself and his dependents, the State again pays one-half of the cost for the employee's coverage and also pays 35 percent of the cost of covering his dependents. For the current contract year, the employee who covers only himself pays \$1.42 each biweekly payroll period and the State pays \$1.42. If the employee has family coverage, he pays \$4.38 each biweekly pay period and the State pays \$3.01. (Coverage costs more under the GHI and HIP options than under the statewide plan, and since the State contribution is the same as under the statewide plan, the employee's cost is necessarily higher under the two options. For example, the cost of individual coverage under the GHI option is \$2.07 for the employee and \$1.42 for the State, and under the HIP option, \$1.94 for the employee and \$1.42 for the State.)

Chapter 461 states that the health insurance contracts should provide health insurance "for retired State employees and their spouses and dependent children . . . on such terms as the Board may deem appropriate. . . ." As indicated previously, the coverage of active employees who meet the required conditions can be continued after their retirement. To provide coverage for former employees who retired prior to December 5, 1957, the date when the program for the active employees began, the contracts were amended in March 1958. The plan for retired employees embodied in the amendment included only the benefits of parts I and II of the plan for active employees. It did not include the major medical benefits which constitute part III, nor did it make available the GHI and HIP options.

This plan went into effect on July 1, 1958, with approximately 5,600 retired employees enrolled. The retired employee's share of the cost is deducted from his retirement allowance. In order to be eligible to participate, the retired employee must belong to one of six retirement systems maintained and operated by New York State.

A Change in the Law

At the 1958 session of the legislature, a change was made in the original health insurance law to permit local government units in New York State, except New York City, to

CLYDE F. FEHN, M.S., and DARRELL R. MADDOCK, M.S.

EFFECTIVE vector control and sanitation practices permitted large, transient populations attending the 13-day National Boy Scout Jamborees to live, eat, and sleep outdoors free of annoyance from flies and mosquitoes.

Experience gained at the 1953 jamboree in Orange County, Calif., attended by 43,000, and at the 1957 event, in Valley Forge State Park, Pa., attended by 51,000, can be applied to other mass gatherings, such as recreational, educational, and religious encampments, and used in civil defense planning and in natural disasters.

Mr. Fehn is a sanitary engineer and Mr. Maddock is a medical entomologist with the Technical Development Laboratories, Communicable Disease Center, Public Health Service, at Savannah, Ga.

In cooperation with environmental sanitation personnel of State and local health departments, Mr. Fehn was responsible for vector control and related operations at the 1953 and 1957 National Boy Scout Jamborees. Both authors were assigned by the Public Health Service to the Boy Scouts of America for this task.

Both Boy Scout jamboree camps were located in suburban areas near large cities. The Scouts attending were grouped in sections, 36 at the California encampment and 38 at the Pennsylvania one. Each section included approximately 34 troops, and each troop, 4 patrols. A patrol consisted of nine boys and an adult leader.

Each patrol cooked its meals on charcoal grills and used paper plates and other paper items for food service. Every section had a tent commissary for the storage and distribution of food and used three walk-in electric refrigerators, each with a capacity of 150 cubic feet. Camp leaders, firemen, policemen, and maintenance men ate at large tent-covered messes. Each camp had five trading posts equipped with hamburger grills and milk and soft drink dispensing units.

At both jamborees some houseflies from the surrounding areas were attracted to the trading posts and large messes. Only the trading posts in California were screened. Eating sites of patrols were free from flies except in a few

publications

Highlights of the National Conference on Air Pollution, 1958. *PHS Publication No. 618; 1958; 42 pages; 35 cents.*

A summary of the National Air Pollution Conference held in Washington, D.C., in November 1958, this booklet contains a digest of the six discussion sessions and a full report of the recommendations resulting from those sessions.

The topics covered were extent and sources of air pollution; its health, economic, and social effects; and methods, procedures, and administrative aspects of air pollution control.

Included also are excerpts of statements by Secretary of Health, Education, and Welfare Arthur S. Flemming, Surgeon General Leroy E. Burney, and Senator Thomas H. Kuchel, who introduced the first Federal air pollution control legislation in 1955.

Homemaker Services in the United States, 1958.

A nationwide study. *PHS Publication No. 614; 1958; by William H. Stewart, Maryland Y. Pennell, and Lucille M. Smith; 106 pages; 55 cents.*

Twelve descriptive statements. *PHS Publication No. 615; 99 pages; 55 cents.*

Homemaker services provided by about 150 agencies in continental United States are reported in the first of these publications. The nationwide study analyzes personnel policies and practices, administration, and policies governing service.

For the approximately 1,700 homemakers employed in these agencies, data on geographic distribution, training and experience, and work schedules are presented. Characteristics of families served as well as sources of referral and services performed by homemakers are also described.

Summary statistics for the study week and for the previous year show

the volume of service and sources of funds for public and for voluntary agencies.

The programs described in the second publication illustrate major variations in organization, administration, and practices among the agencies providing homemaker services. Information on historical background, administration, policies and practices, advisory committees, financing, and evaluation is included in these statements, prepared by the individual agencies.

These publications should be helpful to persons interested in establishing new programs or improving existing ones.

Selected Materials on Environmental Aspects of Staphylococcal Disease. *PHS Publication No. 616; 1959; 289 pages; \$1.50.*

Papers dealing with specific problems of hospital environment and lists of additional readings, audiovisual training aids, and sources of assistance are compiled for use as a reference and guide in developing training programs.

Major topics covered are building construction, water supply and liquid waste disposal, air contamination control and dust suppression, housekeeping and maintenance, and disinfection and sterilization.

Health Statistics From the U.S. National Health Survey. Acute conditions, incidence and associated disability, United States, July 1957-June 1958. *PHS Publication No. 584-B6; 1958; 47 pages; 35 cents.*

Incidence rates are estimated for infectious and parasitic diseases; respiratory and digestive disorders; fractures, dislocations, sprains, and strains; contusions, superficial injuries, open wounds, and lacerations; other current injuries; and all other acute conditions.

Data are given by age, sex, various severity criteria, and calendar quarter. Disability is shown in bed-days, work-loss days, and school-loss days.

Thirty-seven detailed tables and nine graphs are included. Two appendixes present technical notes on methods and definitions of terms.

Protecting Crops and Consumers. The Food and Drug Administration's pesticide control program. *FDA Leaflet No. 6; 1958; 11 pages.* Directed to farmers, agricultural leaders, and shippers of fresh fruits and vegetables. Designed to promote compliance with Federal law restricting amounts of pesticide residues which may remain on food crops. Defines "tolerance," presents rules for grower and packer-shipper, and outlines consequences of non-compliance with the law.

The Scientist in the Food and Drug Administration. *FDA Publication (unnumbered); 1958; by Robert S. Roe; 24 pages.*

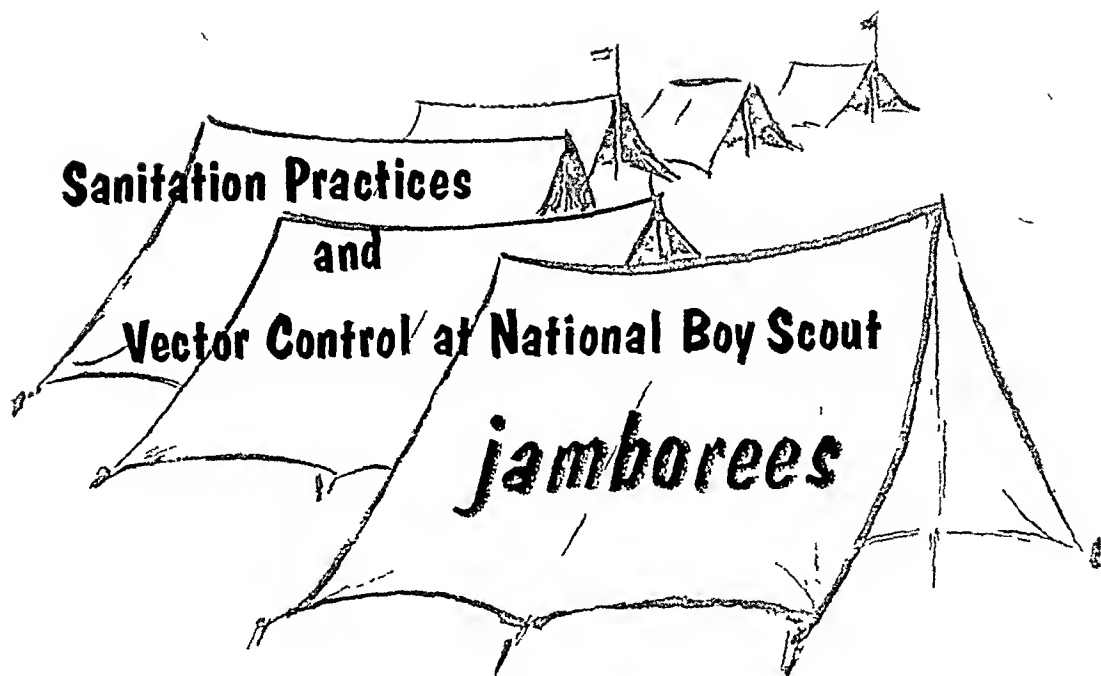

Directed to college seniors and graduates, this illustrated recruiting brochure describes opportunities to use scientific training in positions offered in Washington, D.C., and 17 other major cities.

Work in the fields of food and nutrition, pharmaceutical chemistry, pharmacology, antibiotics, and cosmetics is discussed. Included also are outlines of the functions of the administrative scientists and the field service.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared with Federal support.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Office of Information, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

CLYDE F. FEHN, M.S., and DARRELL R. MADDOCK, M.S.

EFFECTIVE vector control and sanitation practices permitted large, transient populations attending the 13-day National Boy Scout Jamborees to live, eat, and sleep outdoors free of annoyance from flies and mosquitoes.

Experience gained at the 1953 jamboree in Orange County, Calif., attended by 43,000, and at the 1957 event, in Valley Forge State Park, Pa., attended by 51,000, can be applied to other mass gatherings, such as recreational, educational, and religious encampments, and used in civil defense planning and in natural disasters.

Mr. Fehn is a sanitary engineer and Mr. Maddock is a medical entomologist with the Technical Development Laboratories, Communicable Disease Center, Public Health Service, at Savannah, Ga.

In cooperation with environmental sanitation personnel of State and local health departments, Mr. Fehn was responsible for vector control and related operations at the 1953 and 1957 National Boy Scout Jamborees. Both authors were assigned by the Public Health Service to the Boy Scouts of America for this task.

Both Boy Scout jamboree camps were located in suburban areas near large cities. The Scouts attending were grouped in sections, 36 at the California encampment and 38 at the Pennsylvania one. Camp leaders, firemen, policemen, and maintenance men ate at large tent-covered messes. Each camp had five trading posts equipped with hamburger grills and milk and soft drink dispensing units.

At both jamborees some houseflies from the surrounding areas were attracted to the trading posts and large messes. Only the trading posts in California were screened. Eating sites of patrols were free from flies except in a few

Highlights of the National Conference on Air Pollution, 1958. *PHS Publication No. 648; 1958; 42 pages; 35 cents.*

A summary of the National Air Pollution Conference held in Washington, D.C., in November 1958, this booklet contains a digest of the six discussion sessions and a full report of the recommendations resulting from those sessions.

The topics covered were extent and sources of air pollution; its health, economic, and social effects; and methods, procedures, and administrative aspects of air pollution control.

Included also are excerpts of statements by Secretary of Health, Education, and Welfare Arthur S. Flemming, Surgeon General Leroy E. Burney, and Senator Thomas H. Kuchel, who introduced the first Federal air pollution control legislation in 1955.

Homemaker Services in the United States, 1958.

A nationwide study. *PHS Publication No. 644; 1958; by William H. Stewart, Maryland Y. Pennell, and Lucille M. Smith; 106 pages; 55 cents.*

Twelve descriptive statements. *PHS Publication No. 645; 99 pages; 55 cents.*

Homemaker services provided by about 150 agencies in continental United States are reported in the first of these publications. The nationwide study analyzes personnel policies and practices, administration, and policies governing service.

For the approximately 1,700 homemakers employed in these agencies, data on geographic distribution, training and experience, and work schedules are presented. Characteristics of families served as well as sources of referral and services performed by homemakers are also described.

Summary statistics for the study week and for the previous year show

the volume of service and sources of funds for public and for voluntary agencies.

The programs described in the second publication illustrate major variations in organization, administration, and practices among the agencies providing homemaker services. Information on historical background, administration, policies and practices, advisory committees, financing, and evaluation is included in these statements, prepared by the individual agencies.

These publications should be helpful to persons interested in establishing new programs or improving existing ones.

Selected Materials on Environmental Aspects of Staphylococcal Disease. *PHS Publication No. 646; 1959; 289 pages; \$1.50.*

Papers dealing with specific problems of hospital environment and lists of additional readings, audiovisual training aids, and sources of assistance are compiled for use as a reference and guide in developing training programs.

Major topics covered are building construction, water supply and liquid waste disposal, air contamination control and dust suppression, housekeeping and maintenance, and disinfection and sterilization.

Health Statistics From the U.S. National Health Survey. Acute conditions, incidence and associated disability, United States, July 1957-June 1958. *PHS Publication No. 584-B6; 1958; 47 pages; 35 cents.*

Incidence rates are estimated for infectious and parasitic diseases; respiratory and digestive disorders; fractures, dislocations, sprains, and strains; contusions, superficial injuries, open wounds, and lacerations; other current injuries; and all other acute conditions.

Data are given by age, sex, various severity criteria, and calendar quarter. Disability is shown in bed-days, work-loss days, and school-loss days.

Thirty-seven detailed tables and nine graphs are included. Two appendices present technical notes on methods and definitions of terms.

Protecting Crops and Consumers. The Food and Drug Administration's pesticide control program. *FDA Leaflet No. 6; 1958; 11 pages.* Directed to farmers, agricultural leaders, and shippers of fresh fruits and vegetables. Designed to promote compliance with Federal law restricting amounts of pesticide residues which may remain on food crops. Defines "tolerance," presents rules for grower and packer-shipper, and outlines consequences of non-compliance with the law.

The Scientist in the Food and Drug Administration. *FDA Publication (unnumbered); 1958; by Robert S. Roe; 24 pages.*

Directed to college seniors and graduates, this illustrated recruiting brochure describes opportunities to use scientific training in positions offered in Washington, D.C., and 17 other major cities.

Work in the fields of food and nutrition, pharmaceutical chemistry, pharmacology, antibiotics, and cosmetics is discussed. Included also are outlines of the functions of the administrative scientists and the field service.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared with Federal support.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Office of Information, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

Each troop had a privy consisting of two toilets and one urinal in an unpainted wooden riser box enclosed by a tent.

In California it became necessary to spray the privies with 2 percent chlordane emulsion for the control of black widow spiders. By the end of the encampment several of the older privies had begun to produce houseflies. Large pit privies, used for male visitors, were difficult to maintain and were major fly attractants. Several were producing houseflies by the last day of the encampment.

Chemical toilets, furnished and serviced by a commercial firm, were provided for female visitors in California and for all visitors and headquarters staff members in Pennsylvania. At the 1957 jamboree, 110 chemical toilets were augmented by 22 tent-enclosed men's trough urinals discharging into small seepage pits. Both the chemical toilets and the tented urinals were highly satisfactory. It was not necessary to spray the bored hole privies, and vectors did not prove to be troublesome.

The majority of the Scouts slept on the ground in two-man tents. In California boys

were bitten by ants and were in fear of being bitten by black widow spiders. In Pennsylvania 186 cases of extremely painful ear invasions by adult beetles (*Scarabaeidae*) occurred in sleeping Scouts (1). The principal beetle involved was *Autoserica castanea* Arrow. There were a few invasions by *Cyclocephala borealis* Arrow. Cotton ear plugs were used as a control measure. No cases were reported in persons sleeping on cots.

Insecticide-Impregnated Cords

Adult houseflies were attracted to both camps from surrounding breeding sources. At the 1953 jamboree 2 percent chlordane emulsion applied to resting places at the trading posts and large messes controlled the flies. In 1957 flies were controlled more easily and effectively with 2,100 feet of commercially produced cotton cord $\frac{3}{32}$ inch in diameter, impregnated with parathion and Diazinon, which cost \$28. Cords were easily installed in the trading posts and large messes with a hand-operated staple tacker. The cords, about 20 linear feet per 100 square

A stake-truck is unloaded at the site of the sanitary landfill in Pennsylvania. A front-end loader pulls at the front end of the tarpaulin, rolling out refuse.

After meals Scouts put garbage in heavy paper bags inside plastic-coated cans. Later bags were placed on tarpaulins atop trucks.

instances when sanitation lapsed temporarily. Some rodents and ants appeared in the commissaries and large messes.

Water was obtained from large metropolitan supplies. The maximum consumption at the California jamboree was about 750,000 gallons or 17 gallons per person per day. Meters were not used in 1957; however, the system was designed for a maximum flow of 30 gallons per person per day. In California, leaks caused by troublesome above-ground water main couplings created mosquito-breeding areas. This hazard was reduced in Pennsylvania by placing the mains in trenches at least 6 inches deep.

Each section had a cold water shower with the waste water piped to a remote low point, and a four-spigot water drawing station built over a small seepage pit. Water was carried in 5-gallon gasoline cans to two Lister bags, one for drinking water and one for washing, at each troop site.

For the disposal of waste wash water each troop site had a small sump covered with an expanded metal grate; large messes and trading posts used covered seepage pits. No difficulties with vectors developed around the water drawing stations, the Lister bags, or the disposal facilities for waste water.

Refuse Disposal

The refuse from the entire camp amounted to 650 cubic yards per day in California and 1,000 cubic yards per day in Pennsylvania. In California each troop was provided with three garbage cans which were placed at a central point for collection each night. Operational difficulties experienced with this system included scattering of refuse at the central storage points because of reduced nighttime supervision, excessive noise during sleeping hours, and failure to collect all refuse because of greater nighttime absenteeism of collection employees.

In Pennsylvania a more efficient system was used. Each troop was issued an inexpensive, 22-gallon, plastic-coated metal garbage can, and received a daily supply of four 50-pound wet-strength paper bags. Garbage was placed in the bags after each meal, and the bags were tied and taken to a 1½-ton stake-body truck, stationed at each section.

Each truck was equipped with a canvas tarpaulin with one end fastened to the tailgate and the other end tied by ropes to the top of the forward stakes. Refuse bags were placed on the top of the tarpaulin, and the trucks hauled them to the disposal site three times a day. The vehicles were unloaded by pulling on the upper end of the tarpaulin with a front-end loader, thus rolling out the refuse. Each truck bed was sprayed once a day with a mixture of 2 percent chlordane emulsion and a deodorant. There were few sanitation lapses in this system and no vector problems.

In California refuse was disposed of partly by burning, which attracted flies, and partly by sanitary landfill. At the 1957 jamboree all refuse was handled easily, without burning, in one sanitary landfill, and there were no difficulties with vectors.

Prior to the jamborees three holes, each 1 foot in diameter and 6 feet deep, were power-bored for each privy at the encampment site.

Cotton cord impregnated with parathion and Diazinon controls houseflies at the unscreened trading post. Cord is strung horizontally above the refrigerator to the serving counter.

Equipment and Staff

A 4-wheel drive jeep equipped with power take-off mechanism, a 55-gallon stainless steel tank, a 50 p.s.i. insecticide pump, 150 feet of $\frac{3}{4}$ -inch rubber hose, and a spray gun, adjustable from solid spray to a fine mist, were suitable for most insect control operations. Hand spray cans were used to reach places inaccessible to the jeep. In addition, spray cans were lent to section leaders desiring to spray their areas.

All control work was done or closely supervised by professional staff members of the Public Health Service or the respective State health departments. Particular care was exercised when pesticides were applied or exposed near food. Each jamboree required four full-time staff members for vector control work.

Summary

The jamborees demonstrate that it is possible to eat, sleep, and live in the open free of annoyance from flies and mosquitoes. Excellent basic sanitation practices supplemented by the judicious application of pesticides were responsible for the control of these vectors.

Commercially prepared, insecticide-impregnated cords proved to be a cheap, easily installed, and effective housefly control measure in Pennsylvania. A power sprayer equipped with a long hose and mounted on a 4-wheel drive jeep was ideal for most insect control operations. Chlordane emulsion proved to be a satisfactory, broad spectrum insecticide.

Warfarin served as a safe, effective rodenticide against many different species of rodents.

Elevated beds, such as cots, would be most useful in reducing contact with beetles, crawling insects, and small rodents. Certain beetles warrant consideration as public health nuisances in planning future encampments.

feet of floor area, were draped horizontally between tent posts or counter struts, or both, at heights of 8 to 10 feet. Vertical drop sections were not used. This amount of cord is somewhat less than the 30 linear feet per 100 square feet recommended by the Public Health Service (2-5).

Houseflies were repelled for about 5 minutes after the cord was hung, but subsequently they rested readily on the treated cord during the day and night. Control was obtained within a few hours. Excessive temperatures of hamburger grills in two trading posts caused grease to be deposited on the cords, making it necessary to replace them after 7 days.

Mosquitoes and Other Insects

Mosquitoes were controlled successfully at their breeding sites at both jamborees with DDT or chlordane emulsion larvicide applied by power sprayers. The California camp was located within the geographic jurisdiction of the Orange County Mosquito Abatement District and thus control work by Boy Scout authorities was not necessary.

The Pennsylvania area had no local mosquito control program. Accordingly, larviciding measures were started 5 weeks before the encampment, with 2 percent DDT or 1 percent chlordane emulsion. Sanitarians from the Pennsylvania Department of Health and the authors used a Public Health Service jeep-mounted power spray unit for this work.

Ants, black widow spiders, ticks, wasps, sand fleas, rodent ectoparasites, and a variety of other insects were controlled satisfactorily with 2 percent chlordane emulsion applied as a residual to the point of runoff. Chlordane is a broad spectrum insecticide of great usefulness in temporary encampments.

In 1946, plague was found in squirrel fleas taken from the encampment area in Orange County, Calif. The Orange County Department of Agriculture, in close cooperation with California health authorities, conducted extensive wild rodent eradication campaigns in 1952 and 1953. Just before the jamboree 5 percent dieldrin dust was applied by aircraft over the entire camp at the rate of 25 pounds of dust per acre to control rodent ectoparasites. These measures were highly effective.

Rodent Control

Warfarin was effective in safely controlling a wide variety of rodents including domestic rats, house mice, field mice, and gophers. Small, shallow paper plates containing 0.025 percent warfarin in cornmeal or rolled oats were placed in protected locations. Specially constructed bait stations were not used.

A few rodent bites, mostly on the hands, occurred when boys attempted to make pets of wild rodents found in the area or brought from home for trading.

When the nocturnal noise of rodents annoyed tent occupants, 2 percent chlordane emulsion was applied to the burrows, and openings were closed with earth. This treatment was effective in eliminating the annoyance. The chlordane probably acted as a repellent to drive the rodents to a new home in nearby woods or ravines and killed any rodent ectoparasites left behind.

Insecticide-impregnated cord is installed in a food serving area. A staple tacker is used to attach the cord to counter struts and posts.

WHO *looks ahead*

The next 10 years of WHO was the theme of the sixth annual meeting of the National Citizens Committee for the World Health Organization, in St. Louis, Mo., on October 29, 1958.

Dr. Leonard W. Larson, chairman of the board of trustees of the American Medical Association, said that the principal challenges of the next 10 years will be to clarify the relationship between medicine and world peace, to control and eliminate communicable diseases, to construct hospitals and medical educational institutions in underdeveloped countries, and to train leaders on their native soil.

Dr. Leroy E. Burney, Surgeon General of the Public Health Service, cited evidence of the new and vigorous support of international health by this Nation. He observed that public health workers must have a high sense of mission in international health, a field that requires many more well-qualified workers, especially those with flexibility enough to feel at home anywhere. This means, he said, that many of us must learn to accept the entire world as our field of responsibility.

Excerpts from the St. Louis conference have been published by the National Citizens Committee in New York City. Four of the papers presented at the conference are summarized below.

Mortality From Infections Blamed on Malnutrition

Malnutrition plays a much greater role in the high mortality of young children in some areas of the world than has been hitherto appreciated, averred Dr. Nevin S. Scrimshaw, regional adviser in nutrition, Pan American Sanitary Bureau, Regional Office for the Americas of the World Health Organization.

Scrimshaw observed that the synergistic relationship between malnutrition and infection must be understood as a basis for future control programs. The high death rate for children under 5 years of age in underdeveloped countries is often attributed to infections, but, he said, field studies suggest that perhaps a third of these children are dying with the signs and

symptoms of malnutrition, usually precipitated by an acute infectious episode. A considerable proportion of the other two-thirds, Scrimshaw added, are dying of infections which would not ordinarily be fatal to a well-nourished child.

Kwashiorkor

Efforts to reduce the incidence of kwashiorkor, a serious nutritional disease of children, were cited by Scrimshaw as evidence that the recommendations of expert WHO committees stimulate research and promote effective control.

Prior to the first meeting of the Joint Expert Committee on Nutrition of the Food and Agricultural Organization and the World Health Organization, Scrimshaw said, no one was aware that kwashiorkor had a common nature or that the syndrome resulted from protein

control with parathion and Diazinon impregnated cords in dairy barns and dining halls. J. Econ. Ent. 50: 24-27, February 1957.

Epidemiological Notes

Septicemia

Since 1948 there has been a perceptible increase in the number of deaths from septicemia. While the total is not large when compared with numbers of deaths from certain chronic diseases or tuberculosis, it is now larger than the number for most notifiable diseases. The mortality rate for septicemia doubled (0.4 to 0.8 per 100,000 population) during the period from 1949 to 1957.

As shown in the table, the number of deaths from staphylococcal septicemia rose steadily in the same period. On the other hand, the frequency of deaths from streptococcal septicemia declined while the number for pneumococcal septicemia remained stationary. The category for other specified types, which includes among other infections those caused by pseudomonas and coliform organisms, also increased substantially. A large proportion, more than two-thirds of the total septicemia deaths, were not identified as to type. These are designated as unspecified. The number of deaths in this category increased, especially in 1956 and 1957.

Sepsis of the newborn, that is, in infants under 1 month of age, is not included in the above categories. The numbers of deaths from this cause are shown in the last column. The trend in this group is also upward.—Dr. CARL C. DAUER, *medical adviser, National Office of Vital Statistics, Public Health Service.*

Number of deaths from septicemia and pyemia in the United States, 1 month of age and over (053)							Sepsis under 1 month (767-768)

1949.....	587	54	92	16	27	398	307

NOTE: Numbers in parentheses refer to International Classification of Diseases.

Information that is being sought for diseases such as atherosclerosis and cancer is at hand for today's major infectious diseases. What is needed, McDermott pointed out, is information that is much more precise and in many ways more subtle. It is a mistake, he said, to consider tuberculosis or kwashiorkor, for example, as individual diseases. They are "hyphenated diseases," for when a child dies of tuberculosis, what he really dies of is tuberculosis-malnutrition.

Scanty Background

McDermott described the scientific background of hyphenated diseases as appallingly scanty, but pointed out that some studies are underway to offset this deficiency. He cited research by Dr. René Dubos and by Dr. Loyd Hedgecock which has shown that mice immunized with BCG could have their immunity either totally suppressed or fully expressed by alterations in their diet.

Studying the transmission of tuberculosis would be another valid research endeavor, McDermott said. He observed that little research is being done at present on this because in the economically developed countries tuberculosis can be controlled without exact knowledge as to how transmission takes place. Yet today, in many places, he said, a single-room, one-floor hut houses 12 adults and children, several of whom are breathing tuberculosis bacilli which have lost their pathogenicity for guinea pigs and monkeys but have retained it for mice. It would be to our advantage, McDermott said, to set up chambers recreating these conditions and studying and defining them so that we might know what happens.

Two Points

McDermott called attention to the fact that the development of vaccines and drugs has made it possible to place in the hands of an illiterate villager the power to deliver a more effective treatment to a person critically ill of pneumonia, meningitis, or tuberculosis than could have been done by the most highly skilled physician of 25 years ago. We have been slow in facing up to what this situation implies, he said, and also

in exploiting it for man's benefit. He suggested that a greatly expanded research effort is needed on the medical, sociological, and economic aspects of this situation.

McDermott also questioned the common assumption that when a particular infection in an underdeveloped country is under control, the people will inevitably face the same diseases that we now have. Is this necessarily the case? he asked. Is it not possible that wholly different patterns of disease balance might emerge in a somewhat sanitized environment which is still predominantly rural, rustic, and otherwise unchanged? This, too, he said, is an important matter for WHO research, especially by social scientists.

In closing, McDermott emphasized the need for research on what will continue to be important problems of the WHO program. Basic research in health, for WHO's purposes, should broaden our understanding, while, at the same time, it should prove to have broad application, he concluded.

Hazards of Living Worse Than Dangers of Dying

We must shift our emphasis from the dangers of dying to the hazards of living, for in today's world the solution of one health problem invariably creates others, declared Dr. John W. Knutson, chief dental officer, Public Health Service.

In less fortunate parts of the world, he said, teeming millions are being kept alive, but they are malnourished or starving, ill-housed or unhoused, and illiterate.

Knutson observed that international health efforts are not free of political implications. Standards of living and levels of consumption, he said, exert an important impact on political thinking and attitudes. Malnourished bodies and sick minds are not a sound base for rational citizenship in a peaceful world.

Knutson also pointed out dental health needs abroad. Many people, he said, cannot afford refined dental services such as gold inlays or even fillings, but they still need relief from pain and infection.

malnutrition. Clinicians, largely unaware of the work of others, were publishing reports in many countries. Public health authorities did not recognize the disease.

As a result of the expert committee's recommendations, researchers were sent to Africa and to Central and South America. Their reports made it evident to nutritionists, pediatricians, and persons concerned with child health in more than 60 countries in which kwashiorkor occurs that the disease was a major cause of the high mortality in preschool children and that it was a public health problem for which solutions had to be found.

Scrimshaw pointed out that solutions have been expedited by WHO's policy of providing fellowships and travel grants, seeing to it that knowledge is pooled, and trying out preventive measures on a coordinated basis. As a result, he said, first class research has been completed, human resources have been developed to combat deficiency diseases, and campaigns against protein malnutrition have "snowballed." Active work on the development of additional protein-rich foods for the supplementary and mixed feeding of infants and young children has taken place in more than 25 centers in 18 of the countries in which protein malnutrition is acute.

Other Work in Nutrition

A particular feature of WHO's program in nutrition, Scrimshaw noted, is the attention given to developing the technical capacities of individual workers in areas of great need. The real underdevelopment of the so-called technically underdeveloped countries, he said, is the shortage of persons educated and experienced in using the resources in their areas.

WHO has also made a significant contribution in the field of nutrition by using consultants. Consultants, Scrimshaw observed, are particularly useful in disseminating current knowledge to local medical and health workers and in helping countries devise plans to meet their specific needs.

Recommendations

Scrimshaw recommended that in the future WHO seek:

- To increase the number and competence of trained personnel in underdeveloped countries.

- To finance doctorate programs in public health and postdoctorate training for periods beyond the conventional year.

- To see that consultants who are brought into a region to give special assistance turn their functions over to local people as soon as possible.

- To help develop the human resources of the countries in which international agencies are working.

- To give more assistance to member countries of WHO in preventing toxicity of intentional food additives, and to help reduce acute nutritional problems which arise when there is a changeover from foods prepared by indigenous means to foods prepared in accordance with modern food technology. (Infantile beriberi occurred in the villages of some south-east Asian countries when power-driven rice mills were introduced.)

- To enlarge the permanent nutrition staffs of WHO and PASB to enable them to respond to increasing demands from health authorities for guidance.

Prognosis

Scrimshaw stated that information from studies of the effects of nutrition on differences in the prevalence of chronic disease will result in regimens conducive to greater longevity and better health in older persons.

He also envisioned nutrition as becoming an increasingly routine health activity, with current, specific nutritional problems gradually being overcome.

Emphasizes Applicability Of Basic Research

The research program of the World Health Organization should concern itself with providing as broad a scientific base as possible from which to mount successful attacks on today's major diseases, according to Dr. Walsh McDermott, professor of public health and preventive medicine at the Cornell University Medical College.

The major diseases, he said, are neither obscure nor exotic; they are commonplace diseases.

At present, malaria eradication is complete or far advanced in 16 countries. Eradication has begun in 45 and is planned in 14. To protect their own investments, the national health administrations in the later stages of eradication want to prevent the importation of malaria, and, where malaria is present or a potential threat, to avoid the introduction of a foreign species of vectors or insecticide-resistant vectors.

The United States has taken the lead in supporting malaria eradication and cannot afford to see it fail or be unnecessarily handicapped,

Soper asserted. But eradication from the world requires supplies, equipment, technical orientation, and labor which many malarious areas cannot supply and cannot be expected to supply for themselves.

Within the next 10 years malaria can be eradicated from most of the infected areas if areas that were previously infected and those which become free of the disease support adequately, both technically and financially, the present eradication campaigns coordinated by the World Health Organization.

Water Pollution Control

Statute authorizing Water Pollution Control Board to classify waters in accordance "with considerations of best usage in the interest of the public" held to establish sufficiently definite standards for administrative action. *Application of City of Utica*, 177 N.Y.S. 2d 47 (Supreme Court of New York, Appellate Division, 1958).

The City of Utica sought to prohibit the State Water Pollution Control Board from proceeding with a hearing in respect to alleged pollution of the Mohawk River by discharges from municipal sewers of the city in violation of standards of water purity promulgated by the board pursuant to State law, on the ground that the law constituted an invalid delegation of legislative power in violation of the State constitution.

The statute directed the board to classify the waters of the State "in accordance with considerations of best usage in the interest of the public" taking into consideration factors such as current usage, extent of present pollution, and the limitations on specific pollutants set out in the statute.

In upholding the board and the statute, the court noted that under the State law the classification of waters and the water quality standards were to be adopted only after public hearing on notice to the municipalities and others concerned, and the actions of the board were made subject to judicial review.

It quoted with approval the rule that where the legislature "legislated on the subject as far as was reasonably practicable, and from the necessities of the case was compelled to leave to executive officials the duty of bringing about the result pointed out by the statute, the functions of the administrator, even where great latitude is granted, will be held administrative and lawful."

Returning to the statute, the court held that in the light of the express recognition in the law by the legislature that "due to variable factors, no single standard of quality and purity of the waters is applicable to all waters of the State or to different segments of the same waters," and considering the breadth and highly technical nature of the problem, the legislature could scarcely have devised more definite and specific standards. Accordingly, it held that the statute provided definite and sufficient standards to guide and, at the same time, to control and limit the board in the exercise of the discretion necessarily committed to it.

In Burma, he said, only 19 qualified dentists are available to serve the needs of 19 million people. It is here, he brought out, that queues of people can be seen in search of relief from dental pain and distress. It is here and in similar countries that the distressing complications of well-intended but grossly septic ministrations by untrained and unequipped local practitioners can be observed. But most important, it is here that there is little or no semblance of proposals or plans for action which will foster the evolution of a cadre of dental service personnel so that the future situation will be better than the present.

Multinational Effort Needed To Achieve Eradication

The successful eradication of a disease or vector requires funds and support from each country where a possible seedbed of infection exists, asserted Dr. Fred L. Soper, director emeritus, Pan American Sanitary Bureau, Regional Office for the Americas of the World Health Organization.

Although eradication is not a new concept, it is a new weapon because the governments of the world are beginning to collaborate in solving common health problems through such agencies as the World Health Organization, he stated.

The first such international effort was the commitment made by the nations of the Americas in 1947 to eradicate the urban vector of yellow fever, the *Aedes aegypti*. Soper traced this joint action to efforts to prevent reinfestation of Brazilian cities that had been freed of the vector.

Brazil's National Yellow Fever Service had shown that it was cheaper to eradicate the mosquito from its peripheral haunts than it was to maintain permanent vigilance against its reintroduction into major cities. The service was committed in 1940 to eradicate the vector from all parts of the country. Within 6 years eradication was so successful that Brazil's major concern was reinfestation not only from countries sharing its borders but also from more distant nations that might reinfest its neighbors.

"We now have it within our power to eradicate from the face of the earth that age-old scourge of mankind: malaria. We are embarking with other nations in an all-out, 5-year campaign to blot out this curse forever. We invite the Soviets to join with us in this great work of humanity."—DWIGHT D. EISENHOWER, January 9, 1958.

By committing themselves to eradication in 1947, the countries of the Americas were not only protecting their own people, but they were recognizing the right of Brazil to be protected from reinfestation, Soper said. This experience with *A. aegypti* illustrates that once eradication begins locally, the threat of reinfestation or reinfection from the periphery generates pressure to expand eradication.

Similarly, the U.S.S.R. proposal at the Eleventh World Health Assembly to eradicate smallpox worldwide within 5 years is based on the fact that once smallpox had disappeared from Soviet territory, the machinery and expense of maintaining protection for its population would be unnecessary if the disease were eradicated from the rest of the world.

By voting funds for the national malaria eradication campaign in 1947, the United States Congress committed the Government to a continuing interest in the occurrence of malaria in Mexico, Korea, and all parts of the world from which the United States may be reinfected, Soper declared.

Eradication has emphasized the interdependence of countries in protecting areas freed of malaria. Venezuela found it had a stake in the eradication of malaria in Colombia, Brazil, the Guianas, Trinidad, and even Africa.

In 1954 the delegate of France to the 14th Pan American Sanitary Conference asked how a country once freed of malaria could protect itself against reintroduction of the disease. In the final analysis, Soper said, the only answer is "by joining with all the countries of the world in financing the elimination of the remaining seedbeds of infection wherever they may be."

Malaria, a local endemic disease a decade ago, has become as important to quarantine authorities as smallpox, yellow fever, cholera, plague, and typhus.

At present, malaria eradication is complete or far advanced in 16 countries. Eradication has begun in 45 and is planned in 14. To protect their own investments, the national health administrations in the later stages of eradication want to prevent the importation of malaria, and, where malaria is present or a potential threat, to avoid the introduction of a foreign species of vectors or insecticide-resistant vectors.

The United States has taken the lead in supporting malaria eradication and cannot afford to see it fail or be unnecessarily handicapped,

Soper asserted. But eradication from the world requires supplies, equipment, technical orientation, and labor which many malarious areas cannot supply and cannot be expected to supply for themselves.

Within the next 10 years malaria can be eradicated from most of the infected areas if areas that were previously infected and those which become free of the disease support adequately, both technically and financially, the present eradication campaigns coordinated by the World Health Organization.

Water Pollution Control

Statute authorizing Water Pollution Control Board to classify waters in accordance "with considerations of best usage in the interest of the public" held to establish sufficiently definite standards for administrative action. *Application of City of Utica*, 177 N.Y.S. 2d 47 (Supreme Court of New York, Appellate Division, 1958).

The City of Utica sought to prohibit the State Water Pollution Control Board from proceeding with a hearing in respect to alleged pollution of the Mohawk River by discharges from municipal sewers of the city in violation of standards of water purity promulgated by the board pursuant to State law, on the ground that the law constituted an invalid delegation of legislative power in violation of the State constitution.

The statute directed the board to classify the waters of the State "in accordance with considerations of best usage in the interest of the public" taking into consideration factors such as current usage, extent of present pollution, and the limitations on specific pollutants set out in the statute.

In upholding the board and the statute, the court noted that under the State law the classification of waters and the water quality standards were to be adopted only after public hearing on notice to the municipalities and others concerned, and the actions of the board were made subject to judicial review.

It quoted with approval the rule that where the legislature "legislated on the subject as far as was reasonably practicable, and from the necessities of the case was compelled to leave to executive officials the duty of bringing about the result pointed out by the statute, the functions of the administrator, even where great latitude is granted, will be held administrative and lawful."

Returning to the statute, the court held that in the light of the express recognition in the law by the legislature that "due to variable factors, no single standard of quality and purity of the waters is applicable to all waters of the State or to different segments of the same waters," and considering the breadth and highly technical nature of the problem, the legislature could scarcely have devised more definite and specific standards. Accordingly, it held that the statute provided *definite and sufficient* standards to guide and, *at the same time*, to control and limit the board in the exercise of the discretion necessarily committed to it.

Obtaining the Physician's Cooperation in Reporting Communicable Disease

DOROTHY T. MAGALLON, M.D.

WHEN a public health physician goes into a community, there are many intangible but very real factors that can spell the difference between his success or failure as a health officer. Gaining the confidence and cooperation of the practicing physicians in the area is certainly an important factor. However, even in a community where relationships are of the best, the reporting of communicable disease is often a distinct problem. The same physician who may extend himself to cooperate with the health department at every possible turn often is not aware of the practical importance of reporting disease. Even though State laws require the reporting of certain diseases, we have come a long way from the day when failure to report such a disease was a crime often punishable by death—death not only to the patient but to his family, friends, and sometimes an entire community.

It is the task of public health people to convince private physicians that the time they spend reporting their cases of communicable diseases is still a worthwhile investment. When these physicians are made to feel that the value received in services to them and their patients is worth the effort expended, few will fail to report.

The first step in that direction may be to

Dr. Magallon, formerly director of communicable and chronic disease control, Louisville and Jefferson County Health Department, Louisville, Ky., is now with the Kentucky State Department of Health. This paper was originally presented at the Southern Branch Meeting of the American Public Health Association in Little Rock, Ark., May 7, 1958.

remind the doctors of the community that the health officer considers service to the private physician and his patients one of his main duties. It is surprising how often the practicing physician thinks of the health officer as someone who looks after the health of indigents and has very little to do with him and his private patients who after all comprise a large segment of the community.

Ideally, a health officer new to an area should visit the doctors in practice there, but this may not be practical in large communities. If a personal visit is not possible then a letter introducing the new health officer and listing some of the services available to the physician through the health department may be effective. The letter should be accompanied by a list of the reportable diseases and might stress the advantages to the private physician and his patient of reporting these diseases rather than the advantages to the health department or even the community as a whole.

Reporting by Telephone

The method of reporting disease must be kept simple. As concise as the morbidity card is, many physicians complain that neither they nor their office staff have the time to fill it in. One solution is to encourage the doctor or someone in his office to make telephone reports.

Telephone reporting actually has a number of advantages. It may give the health officer or his secretary an opportunity to learn about other similar cases by asking a few brief questions. For example, suppose Dr. Brown is reporting to me a case of infectious hepatitis

in a child. I would first ask the doctor how he felt about giving gamma globulin to family contacts. Dr. Brown might say he had not seen much infectious hepatitis and he was not too familiar with the use of gamma globulin in contacts but how did the health department feel about it. At this point I can offer a service to Dr. Brown and his patient by sharing with him the knowledge of gamma globulin's value in hepatitis contacts and by telling him that the health department can supply him with gamma globulin for this purpose. Now if there is one thing that sticks in Dr. Brown's mind about gamma globulin, it is probably the fact that it is very expensive when bought through a pharmaceutical house. If he is sold on its value, you can be sure he will report his next case of infectious hepatitis and request gamma globulin for the contacts.

By this time the doctor may not mind answering a few more questions. When asked if he has heard of any more hepatitis in his neighborhood he may remember that Dr. Smith mentioned a case to him just a few days ago. One more question, "Where does the child go to school?" will round out the picture as far as the health officer is concerned.

This entire conversation takes less than 5 minutes, yet it accomplishes the following important things:

1. The private physician has been made aware of a health department service to him and his patient because he reported a communicable disease. The reporting of that disease now means something more to him than merely satisfying a State law. If for no other reason he may now report a disease just to see what the health department has to offer.

2. The physician has been made to feel that he is an important link between his patients and the health officer whose duty it is to safeguard the health of the entire community.

3. The health officer has found at least one other case of the disease in question and has gained information that will aid him in whatever type of epidemiological investigation he may wish to institute.

From the point of view of everyone concerned this 5-minute telephone conversation has been a good investment of time.

Telephone reporting may be used very prof-

itably when an outbreak of a particular disease is anticipated. For example, in Louisville and Jefferson County, Ky., influenza of any type is not well reported by the physicians. In July 1957, Asian influenza was introduced into the community. To insure adequate reporting during the expected epidemic, a surveillance system was set up shortly after the first cases were proved by laboratory diagnosis. It first became apparent from a sudden marked increase in school absenteeism that influenza was on the upswing in the community. A conservative method of estimating probable cases of influenza from absenteeism in schools and industry was determined and was used throughout the outbreak. In order to supplement reporting through regular channels, each week the office of communicable disease control made telephone calls to the Louisville General Hospital outpatient department, health centers, the State laboratory, and 25 private physicians. These physicians were representative general practitioners and pediatricians from various sections of the city and county. In this way we were able to follow the course of the epidemic and arrive at fairly accurate, although probably conservative, statistics.

This system has been extended to other communicable diseases. When for some reason, perhaps from routine hospital or laboratory reporting, we have cause to believe that a disease is on the increase or may be prevalent in a certain section of the city, we contact the physicians in that area. We then do a check survey of the 25 representative physicians used originally in the influenza surveillance. In effect, they serve as a communicable disease barometer. Information gained in this manner to supplement reports through regular channels gives us a fairly accurate picture of infectious disease in the community.

Special Problems

Venereal disease and tuberculosis reporting present special problems in many areas. In Louisville and Jefferson County, the problems of tuberculosis reporting are magnified because the prevalence of the disease is so high. With a few exceptions the private physicians who treat tuberculosis report both new cases and

trol of this disease. Cooperation between the Louisville and Jefferson County Health Department and the veterinarians had not been of the best for reasons long since lost in antiquity. A number of the veterinarians failed each month to submit duplicate copies of animal vaccination certificates as required by law. A campaign to improve relationships with the veterinarians was started. Special emphasis was placed on animal epidemiology and the importance of the veterinarian's role in the control of rabies. Educational and publicity material coming from the health department stressed the importance of consulting a veterinarian when a pet had been bitten by another animal. Members of the county veterinarian's society were consulted frequently about the control of rabies in animals. The air cleared considerably. Then, a letter was sent out to all small-animal veterinarians in the county.

Here again the letter used the idea of giving something, if only interesting statistics, before asking for something. It also gave a reason for reporting that had nothing to do with State law. Twelve self-addressed stamped envelopes for monthly reporting were enclosed with each letter, thereby making compliance with our request as simple as possible.

After 2 months only 3 veterinarians had failed to send their slips in. These were called by telephone and within 3 weeks each had submitted his certificates. For the first time, 100 percent of the Jefferson County veterinarians are reporting vaccinations. As a fringe benefit of this effort we are getting more reports from the veterinarians of clinically suspected rabies in animals and more animal heads for examination. We feel that our entire rabies control program has benefited.

Basic Ideas

There are many specific problems in reporting to be met in every community. We have found that the following basic ideas have been helpful to us when attacking any of these problems:

1. The public health physician who is fortunate enough to teach medical students or to talk at least occasionally to groups of physi-

cians has a prime opportunity to sell the value of reporting. It is true that few health officers have the opportunity to teach formally; but few lack the opportunity to educate informally if they will only accept the challenge.

2. Any group of doctors appreciates a frank but tactful approach.

3. Practicing physicians are very likely to think first of their patients; if we can show these physicians that they and their patients profit from good reporting, they will report.

4. Most private doctors have a sense of community responsibility but are quite naturally oriented to care for the individual patient. Because of this, they need to be reminded periodically of their importance in community health and the importance of good community health to them and their patients.

5. The idea of offering something (service, information, consultation, special laboratory and treatment procedures) before asking for something is always very appealing.

6. Any method used must be simple and require a minimum of time. Perhaps more important than all of these, the health officer himself must command the respect of his fellow physicians. He must not set himself apart; rather he must get to know the physicians in his community, for if he does his job well he will have occasion to communicate with them frequently, and it is much more difficult to communicate effectively with a stranger than with a friend. The local medical society is often a good focus around which to build such feeling. Many former problems, even difficult ones connected with the reporting of diseases, fade out in the glow of this kind of relationship.

However, no matter how good a relationship the health officer has with the physicians of his community, he will have to face one fact realistically. Rare is the community where physicians, unsolicited, will beat a path to the door of the health department for the sake of reporting communicable diseases. In the matter of reporting, the health officer must be the aggressor. It is his task to find the methods of stimulation which bring results in his community and to apply these methods as often as necessary to keep the reporting of communicable disease at a satisfactory level.

Principles of Reporting Communicable Disease

Although State laws require the reporting of communicable disease, good reporting depends on a mutual understanding of practicing physicians and health authorities.

What do health authorities need? First, prompt, reasonably accurate, and reasonably complete information on certain communicable diseases such as diphtheria and typhoid fever. By such means, remedial or preventive action can be triggered, and policy, legislation, and appropriations shaped.

Next, information on diseases such as psittacosis, brucellosis, and tularemia for which immediate action is less important. Trends in incidence and effects of new types of treatment can be observed and, possibly, controls developed at some future date.

Finally, there is need to know more about unusual occurrences of diseases that are reportable and those for which no individual case report is required. I refer to outbreaks of various kinds. There is a real need for more information on unusual occurrences such as venereal disease in an identifiable group, food poisoning and food infection epidemics, and outbreaks in schools and institutions. This information is needed in order to appraise trends and develop remedial measures.

The physician should be encouraged to feel that his reports set in motion procedures which will benefit both the patient and the community. Health officers build up confidence each time they inform physicians that a case or an outbreak is being investigated, an agent isolated, or control measures instituted. The physician should be made aware that his report on typhoid fever or diphtheria may be

only one of several received. The health agency is in the key position to provide this information and to demonstrate any tie among the reports.

In developing acceptance of this function, the health officer may remind physicians that public health laboratories are at their disposal and encourage their use. Or he may elect, with far-reaching consequences, to develop methods for disseminating information on morbidity.

For one town, newsletters, statistical reports, a few paragraphs in the newspaper may all be appropriate means of carrying the word. A weekly report for an entire State is almost a necessity; some States issue monthly summaries as well. In their weekly reports, some States also describe unusual happenings or present comparisons of disease incidence. Others include information on activities of the health department, on immunization procedures, and the like. In general, Federal agencies follow the same pattern.

Routine statistical reporting in which numbers only are used does not meet the demand for pertinent information. Explanations are needed as well. The circumstances or conditions that led to the occurrence of 10 cases of infectious hepatitis are more suggestive than the number "10." Physicians, and the public as well, wish to know whether reported cases are related in any way, how disease is transmitted, the original source of infection, and elements of immunity, resistance, and recovery. Good reporting, after all, includes the concept of what carries meaning and significance.—CARL C. DAUER, M.D., *medical adviser, National Office of Vital Statistics, Public Health Service.*

followups very poorly. Efforts to improve relationships between the health department and this particular group of physicians have not been too rewarding for many reasons. In an effort to correct this situation a letter which stated the problem frankly was sent out. The health department has many services to offer patients with tuberculosis but, by and large, the chest physicians were not making it possible for their patients to benefit from these services. Therefore, the letter asked the physicians to

suggest ways in which the health department can make these services available to their private patients.

Special problems in reporting arise in any community. In Louisville and Jefferson County, we have found that if these problems are met tactfully but frankly the results can be surprising. Here is how we met such a problem which had to do with rabies control. Rabies in our community is a serious problem, and much time and effort are spent in the con-

trol of this disease. Cooperation between the Louisville and Jefferson County Health Department and the veterinarians had not been of the best for reasons long since lost in antiquity. A number of the veterinarians failed each month to submit duplicate copies of animal vaccination certificates as required by law. A campaign to improve relationships with the veterinarians was started. Special emphasis was placed on animal epidemiology and the importance of the veterinarian's role in the control of rabies. Educational and publicity material coming from the health department stressed the importance of consulting a veterinarian when a pet had been bitten by another animal. Members of the county veterinarian's society were consulted frequently about the control of rabies in animals. The air cleared considerably. Then, a letter was sent out to all small-animal veterinarians in the county.

Here again the letter used the idea of giving something, if only interesting statistics, before asking for something. It also gave a reason for reporting that had nothing to do with State law. Twelve self-addressed stamped envelopes for monthly reporting were enclosed with each letter, thereby making compliance with our request as simple as possible.

After 2 months only 3 veterinarians had failed to send their slips in. These were called by telephone and within 3 weeks each had submitted his certificates. For the first time, 100 percent of the Jefferson County veterinarians are reporting vaccinations. As a fringe benefit of this effort we are getting more reports from the veterinarians of clinically suspected rabies in animals and more animal heads for examination. We feel that our entire rabies control program has benefited.

Basic Ideas

There are many specific problems in reporting to be met in every community. We have found that the following basic ideas have been helpful to us when attacking any of these problems:

1. The public health physician who is fortunate enough to teach medical students or to talk at least occasionally to groups of physi-

cians has a prime opportunity to sell the value of reporting. It is true that few health officers have the opportunity to teach formally; but few lack the opportunity to educate informally if they will only accept the challenge.

2. Any group of doctors appreciates a frank but tactful approach.

3. Practicing physicians are very likely to think first of their patients; if we can show these physicians that they and their patients profit from good reporting, they will report.

4. Most private doctors have a sense of community responsibility but are quite naturally oriented to care for the individual patient. Because of this, they need to be reminded periodically of their importance in community health and the importance of good community health to them and their patients.

5. The idea of offering something (service, information, consultation, special laboratory and treatment procedures) before asking for something is always very appealing.

6. Any method used must be simple and require a minimum of time. Perhaps more important than all of these, the health officer himself must command the respect of his fellow physicians. He must not set himself apart; rather he must get to know the physicians in his community, for if he does his job well he will have occasion to communicate with them frequently, and it is much more difficult to communicate effectively with a stranger than with a friend. The local medical society is often a good focus around which to build such feeling. Many former problems, even difficult ones connected with the reporting of diseases, fade out in the glow of this kind of relationship.

However, no matter how good a relationship the health officer has with the physicians of his community, he will have to face one fact realistically. Rare is the community where physicians, unsolicited, will beat a path to the door of the health department for the sake of reporting communicable diseases. In the matter of reporting, the health officer must be the aggressor. It is his task to find the methods of stimulation which bring results in his community and to apply these methods as often as necessary to keep the reporting of communicable disease at a satisfactory level.

For Tuberculosis Control Programs

TUBERCULOSIS control, despite notable progress in recent years, still demands a sizable share of public health attention in many communities, and the need for sound program statistics is as pressing as ever.

So much information is potentially available for studying the needs and achievements of tuberculosis control programs that great care must be taken to choose appropriate types and amount of data to be collected as service statistics. A health department will want to collect only data that are basic to its own program, in addition to those requested for State and national reports. The statistics selected should indicate the extent to which defined program objectives of tuberculosis control are being achieved. Progressive revisions of a program should of course be anticipated.

From tuberculosis service statistics it should be possible: (a) to indicate the size, composition, and location of the tuberculous population; (b) to determine whether or not the cases that require medical supervision are receiving supervision and the care they need; (c) to study the productiveness of casefinding techniques; and (d) to judge whether or not resources are being used effectively and efficiently.

The Indexes for Interpreting Data given in

this paper and the data items for developing these indexes, given under Statistical Information, are suggested as those which can be most helpful in planning, administering, and evaluating services in tuberculosis control. Neither the indexes nor the data items, however, can in themselves provide sufficient information for complete evaluation. The data must be related to one another and to other available information, and they must be grouped so that a clear picture results. Even then, appropriate decisions can be made only after careful consideration by persons who understand the significance of the findings and can identify pertinent highlights for action.

In some areas, procedures have not been established for collecting basic information, and consequently health agencies are unable to observe certain important local trends. The absence of such information is a deficiency, and health jurisdictions should make every effort to develop adequate records and procedures for the collection of pertinent service statistics.

Indexes for Interpreting Data

The principal quantitative indexes of the tuberculosis problem and selected indexes of the

With this report, the Working Group on Service Programs of the Public Health Conference on Records and Statistics has completed five documents on the collection, analysis, and interpretation of service statistics. These documents are intended to aid in preparing data for planning, administering, and evaluating various public health services.

The first report, appearing in *Public Health Reports* in June 1956, page 519, introduced the series and set forth basic principles governing service statistics. Subsequent reports dealt with health supervision of infants and preschool children (July 1956, page 705), health services for children of school age (September 1956, page 917), and home accident prevention programs (June 1957, page 494).

In preparing this fifth report on statistics for tuberculosis control programs, the working group was assisted by several consultants with special experience in programs of tuberculosis control. The guide had almost reached its present form when the conference was reconstituted in March 1958 as a consultative and collaborative study program. Aided by the Tuberculosis Program, Public Health Service, a study group of the new conference completed the work. Their revisions were based on comments received after distribution of the mimeographed release (Document 438, reproduced by the National Office of Vital Statistics, Public Health Service, De-

partment of Health, Education, and Welfare, Washington 25, D.C.).

Under the title "A Guide for the Collection, Analysis, and Interpretation of Service Statistics in Tuberculosis Control Programs," the document has the endorsement of the following organizations: American Association for Vital Records and Public Health Statistics, the Committee on Public Health Administration and the Statistics Section of the American Public Health Association, and the Association of State and Territorial Directors of Local Health Services. It was endorsed by the president of the American Trudeau Society. The Association of State and Territorial Directors of Public Health Nursing recommends that the guide receive careful attention.

Dr. James E. Perkins, managing director of the National Tuberculosis Association, one of the agencies providing technical consultation in developing the guide, believes that it will be helpful to those responsible for the collection and analysis of meaningful statistical data on tuberculosis. The Committee on Tuberculosis Nursing of the National League for Nursing and the National Tuberculosis Association regards the guide as an important and worthwhile step forward in measuring progress in tuberculosis control.

scope and effectiveness of program operations are given in this section. These indexes can be constructed from the data items listed under Statistical Information, sometimes from only a pair of items and sometimes from several. For example, the first index under Program Operations, casefinding coverage, is in effect a summary obtained by analyzing items selected from Baseline Data, as well as from Data on Program Operations.

The validity of the indexes will depend on the completeness of the component statistical items and the reliability of the statistical procedures used in relating one item to another. If a valid comparison is to be made between indexes for different time periods or different areas, it is

essential that they be based on comparable data uniformly defined, collected, and analyzed.

For most of the indexes, the period of measurement is 1 year; however, in some localities another time interval may be preferred. For example, in areas where there are few cases of tuberculosis, or few deaths, it might be advisable to use 3- to 5-year averages in order to minimize the effects of random fluctuations.

Many of the indexes have been used in reports prepared by various health agencies, such as Reported Tuberculosis Data, released periodically by the Public Health Service. It is therefore possible for a health department to obtain data on other communities for comparison with its own performance.

Many health departments may not find it feasible to tabulate the data required for all the indexes, while others may need additional indexes. The list is intended to be a reasonable compromise.

Definition of Problem

Mortality: Annual rate of tuberculosis deaths per 100,000 population.

Incidence: Annual rate of newly reported active cases per 100,000 population. (The term "active case" in this paper refers to cases classified as active and probably active, as explained in reference 1.)

If casefinding and reporting are reasonably adequate (as indicated by the ratios under Casefinding, below, and in other ways), this rate provides an estimate of the rate at which new cases are actually developing in the population. Where casefinding and reporting are consistent from year to year, this rate reveals the trend of known incidence.

Prevalence of known cases: Rate of known active cases per 100,000 population as of a specified date.

This rate has limited meaning when the percentage of cases for which medical examination reports are overdue is high.

Rate of all known cases, regardless of clinical status, per 100,000 population as of a specified date.

These figures on known prevalence can serve as an estimate of the community's tuberculosis problem. Estimates of total prevalence of tuberculosis cases, including unknown as well as known cases, can be obtained only by special studies, not from service statistics.

Prevalence of infection, as measured by the tuberculin test (2): Percent reacting among all ninth grade students tuberculin tested (and read) during year.

This index can be used to observe long-term trends in the prevalence of infection in the community. It can also be used to identify areas of a city where infection rates tend to be the highest. Lower grades are not suggested because in many parts of the country it is necessary to test adolescents in order to obtain a rate high enough to fulfill these two functions. Higher grades are not recommended because these students are progressively less representative of the community population of similar age.

In some cities the prevalence of sensitivity among first grade children is still great enough to serve these purposes. In such localities it would be useful to test

first grade children as well as those in the ninth grade since the sensitivity level among the younger children is more likely to indicate recent conditions of exposure to infection.

The prevalence of infection among adults should be determined by special studies, and testing of this group should progressively become a part of the regular program of periodic assessment of the tuberculosis problem. In many areas today testing of adults is needed more than testing of school children.

Program Operations

CASEFINDING

Coverage: Of the population in specific high-risk groups or areas, percent screened during year.

Followup of screening program suspects: Of tuberculosis suspects, percent for whom followup was completed within 6 months after the screening program either by establishment of a diagnosis (tuberculosis, other chest disease, or essentially negative) or by other disposition.

Contact examination: Of contacts to new active cases reported during year, percent examined by end of year.

Effectiveness of casefinding programs: Of new active cases reported during year, percent discovered by organized casefinding efforts: chest X-ray surveys, tuberculin testing programs, or contact examination.

Of new active pulmonary cases reported during year with extent of disease specified, percent classified as minimal.

If extent of disease is not specified in a large proportion of cases, the meaning of this item is severely limited.

Of new active cases reported during year, percent first reported by death certificate or at time of death.

USE OF HOSPITALIZATION

Of new active cases reported during year, percent hospitalized for treatment of tuberculosis at any time during year.

Of all known active cases as of a specified date, percent in hospitals for treatment of tuberculosis on that date.

SUPERVISION OF UNHOSPITALIZED CASES

Prescribed treatment: Of unhospitalized active cases on a specified date, percent with no

known drug therapy or other specific treatment prescribed.

Of unhospitalized inactive cases, percent with no known drug therapy currently prescribed.

Medical supervision: Of total unhospitalized cases as of a specified date, percent for which medical examination report is overdue.

This index should also be constructed for active and activity undetermined cases.

Of unhospitalized active cases as of a specified date, percent with no bacteriological examination report within preceding 6 months.

Public health nursing supervision: Of total unhospitalized active and activity undetermined cases as of a specified date, percent with no public health nursing visit within preceding 6 months.

Of unhospitalized active cases with current positive bacteriological findings as of a specified date, percent with no public health nursing visit within preceding 6 months.

Of new active cases reported during year, percent visited by public health nurse within 1 month of report to health department.

A low rate may be caused by lack of prompt referral to the nursing division.

Of cases discharged from hospitals during year, percent visited by public health nurse within 1 month of date of discharge.

A low rate may be caused by the hospital's delay in notifying the health department.

Status on hospital discharge: Of active cases discharged from hospitals during year, percent with positive bacteriological findings at time of discharge.

Of active cases discharged during year, percent discharged against medical advice.

Medical social service: Of unhospitalized active cases referred to social service during a specified period, percent who have received social service during same period.

Vocational rehabilitation: Of cases referred for rehabilitation service during year, percent accepted for rehabilitation.

Terms, Data Sources, Tabulation

Standard terminology. Uniform application of standard terminology is essential in the collection of data. Unless all items that go to make up a total are chosen according to one

definition, the total will not be valid. If different definitions are used at different times or in different places, totals will not be comparable from one time to another or from one place to another.

Definitions for most of the basic terms used in tuberculosis control may be obtained from Diagnostic Standards and Classification of Tuberculosis (2) and from the Report and Recommendations of the Committee on Morbidity Reporting (1). The committee's recommendations are reprinted on the back of the Semiannual Tuberculosis Morbidity Report, a Public Health Service required report (PHS Form 1394, revised 1-52), and in the National Morbidity Reporting Manual of Procedures (3).

Sources of data. Most data in tuberculosis control come from basic records (clinic and hospital, laboratory, nursing, case register, for example), and these must be adequate, accurate and properly correlated if they are to supply the necessary information. Statistical analysis cannot produce results more accurate than the primary data. Public health agencies can do much to refine and improve their own source documents in tuberculosis control and to improve communications with other agencies and institutions. Joint planning can frequently reduce the number of record forms needed and make each more effective and serviceable.

Data on newly reported cases can be obtained from the official morbidity reports and summaries which are made once or twice a year by most local health departments.

The source of prevalence data is the tuberculosis case register, or equivalent records, for which information must be obtained routinely from places providing services to the patient, such as clinics, private physicians, laboratories, hospitals, and nursing offices. Keeping current information on each patient's status should be part of routine operating procedure in maintaining good case supervision. Techniques will vary for obtaining statistical reports reflecting the extent of supervision and current clinical status of known tuberculosis patients.

Mortality data are available from the analysis of death certificates filed with local registrars of vital statistics and forwarded to offices

Counts by cause of death are made by the State vital statistics offices. Information regarding persons with tuberculosis who die of other causes, as well as tuberculosis cases reported for the first time by death certificate, must come from the cooperative efforts of the tuberculosis control and vital statistics offices.

Population figures which are more recent than those reported in the United States decennial census publications may be available from special local censuses or from population estimates periodically prepared by a State or local agency. Each year the May issue of *Sales Management* magazine contains current population estimates and pertinent information on economic status for all counties and major cities.

The hospital facilities office of the State health department can supply information on the number and kinds of hospitals within its jurisdiction, including bed capacity and other pertinent data. Similar information can be found each year in the August issue of *Hospitals* (Journal of the American Hospital Association) and the Public Health Service publication, *Tuberculosis Beds in Hospitals and Sanatoria*. State nursing and medical associations, as well as other professional organizations, and special surveys made by professional organizations provide information on numbers and specialties of medical and paramedical personnel.

Tabulating methods. Tabulating methods must be considered when record forms are designed since the two are related. In selecting the most appropriate method, volume is an important factor. Hand tabulations are not necessarily the least expensive or most accurate. For a moderate quantity of records the marginal punchcard system, with its many applications and flexibility, merits consideration. Machine tabulation is usually recommended for large volume because of its greater speed, accuracy, and flexibility.

Statistical Information

The items listed below provide the information necessary for program measurement as outlined in the section on indexes, plus supplemental information which will permit further

assessment of the tuberculosis problem and adequacy of program activities.

Baseline Data

HEALTH JURISDICTION

1. Total population as of specified date.
2. Population of specified high-risk groups (for example, special geographic areas; admissions to general hospitals; residents and employees of mental, penal, and other "resident" institutions; lower economic groups; and older age groups).
3. Population breakdown by age, sex, race, marital status, urban-rural, geographic location, occupation, and economic status.
4. Health facilities and resources, including (a) number of beds available to tuberculosis patients in general and tuberculosis hospitals; (b) number, location, and patient capacity of chest clinics; (c) number and type of medical and paramedical personnel.

MORTALITY

1. Number of tuberculosis deaths for the year.
2. Tuberculosis deaths by age, sex, race, marital status, geographic location of residence, occupation, and economic status.

INCIDENCE

1. Newly reported active cases for year, including active and probably active in both pulmonary and nonpulmonary classifications of disease (1), by source of report: (a) private physicians, (b) tuberculosis hospitals (public and private), (c) general hospitals, (d) chest clinics, (e) mental institutions, (f) death certificates, (g) transferred from other States, (h) transferred from other local health jurisdictions, (i) other.
2. Newly reported active cases for year by method of discovery (source of referral), such as chest X-ray surveys, tuberculin tests, contact examination, health examination, and self-referral.
3. Newly reported active cases for year by age, sex, race, marital status, geographic location of residence, occupation, and economic status.
4. Newly reported active cases for year by form and extent of disease.

PREVALENCE OF KNOWN CASES

Known tuberculosis cases as of a specified date classified by clinical status: (a) active or probably active (group A); (b) activity undetermined or not specified; (c) inactive or probably inactive but requiring public health supervision (open file only).

PREVALENCE OF INFECTION

1. Total number of persons tuberculin tested (and read), by method of test, by age or school grade, sex, and race, for each population group that warrants special investigation.

2. Number read, by size of induration (in millimeters), by the same classifications.

3. Number considered "positive," by the same classifications.

Data on Program Operations

CASEFINDING

Data should be collected for each population group that warrants special investigation, by age, race, and sex if possible, and for appropriate periods.

Chest X-ray Surveys

1. Number of persons screened.

2. Number of persons with screening films read as suspected: (a) tuberculosis, (b) cardiovascular disease, (c) tumor, (d) other non-tuberculous chest disease.

3. Followup of tuberculosis suspects.

(a) Number diagnosed as tuberculous and reported as new cases, by clinical status.

(b) Number diagnosed as essentially negative for tuberculosis.

(c) Number diagnosed as having nontuberculous disease, by type of disease.

(d) Number with followup incomplete or pending.

Tuberculin Testing

1. Number of persons tested and read.

2. Number of reactors.

3. Number of reactors X-rayed.

4. Number of persons found with suspected tuberculosis.

5. Number diagnosed and reported as new cases, by clinical status.

Contact Investigation

1. Number of close contacts (household and

any other with a history of close contact) to newly reported active and probably active cases.

2. Number of contacts examined by end of year by X-ray or tuberculin tests: (a) diagnosed as tuberculous and reported as new cases, by clinical status; (b) diagnosed as negative for tuberculosis; (c) with incomplete followup.

HOSPITALIZATION

Of new active cases reported during year, number hospitalized for treatment at any time during year.

Hospitalization for diagnosis or observation alone should not be included in this count.

CASE SUPERVISION: TUBERCULOSIS REGISTER

1. Total number of cases in tuberculosis register or its equivalent (current file only) as of specified date:

(a) Cases hospitalized for tuberculosis: (i) in tuberculosis hospitals (including tuberculosis wards of general and chronic disease hospitals); (ii) in mental and penal institutions (only active cases and inactive cases on anti-tuberculosis drug therapy).

(b) Cases hospitalized for other conditions.

Include cases not being treated for tuberculosis but presumably being given appropriate periodic examination by the institution; for example, inactive cases not on drug therapy in mental, penal, and chronic care institutions. If the hospitalization is of short duration—for an appendectomy, for instance—count in the following item.

(c) Cases not hospitalized.

Include those presumed to be outside institutions, plus tuberculosis patients residing in certain institutions, such as nursing homes, who are not being supervised for their tuberculosis by the institution. It is, of course, the responsibility of the health department to see that these patients receive necessary medical supervision and treatment.

2. Clinical status of cases not hospitalized.

(a) Active and probably active.

(b) Activity undetermined (or activity not stated), that is, only those cases which cannot be classified as probably active or probably inactive.

(c) Inactive and probably inactive with current drug prescription.

(d) Inactive and probably inactive without current drug prescription.

3. Medical followup of cases not hospitalized, by clinical status.

of vital statistics in State departments of health. Counts by cause of death are made by the State vital statistics offices. Information regarding persons with tuberculosis who die of other causes, as well as tuberculosis cases reported for the first time by death certificate, must come from the cooperative efforts of the tuberculosis control and vital statistics offices.

Population figures which are more recent than those reported in the United States decennial census publications may be available from special local censuses or from population estimates periodically prepared by a State or local agency. Each year the May issue of *Sales Management* magazine contains current population estimates and pertinent information on economic status for all counties and major cities.

The hospital facilities office of the State health department can supply information on the number and kinds of hospitals within its jurisdiction, including bed capacity and other pertinent data. Similar information can be found each year in the August issue of *Hospitals* (Journal of the American Hospital Association) and the Public Health Service publication, *Tuberculosis Beds in Hospitals and Sanatoria*. State nursing and medical associations, as well as other professional organizations, and special surveys made by professional organizations provide information on numbers and specialties of medical and paramedical personnel.

Tabulating methods. Tabulating methods must be considered when record forms are designed since the two are related. In selecting the most appropriate method, volume is an important factor. Hand tabulations are not necessarily the least expensive or most accurate. For a moderate quantity of records the marginal punchcard system, with its many applications and flexibility, merits consideration. Machine tabulation is usually recommended for large volume because of its greater speed, accuracy, and flexibility.

Statistical Information

The items listed below provide the information necessary for program measurement as outlined in the section on indexes, plus supplemental information which will permit further

assessment of the tuberculosis problem and adequacy of program activities.

Baseline Data

HEALTH JURISDICTION

1. Total population as of specified date.
2. Population of specified high-risk groups (for example, special geographic areas; admissions to general hospitals; residents and employees of mental, penal, and other "resident" institutions; lower economic groups; and older age groups).
3. Population breakdown by age, sex, race, marital status, urban-rural, geographic location, occupation, and economic status.
4. Health facilities and resources, including (a) number of beds available to tuberculosis patients in general and tuberculosis hospitals; (b) number, location, and patient capacity of chest clinics; (c) number and type of medical and paramedical personnel.

MORTALITY

1. Number of tuberculosis deaths for the year.
2. Tuberculosis deaths by age, sex, race, marital status, geographic location of residence, occupation, and economic status.

INCIDENCE

1. Newly reported active cases for year, including active and probably active in both pulmonary and nonpulmonary classifications of disease (1), by source of report: (a) private physicians, (b) tuberculosis hospitals (public and private), (c) general hospitals, (d) chest clinics, (e) mental institutions, (f) death certificates, (g) transferred from other States, (h) transferred from other local health jurisdictions, (i) other.
2. Newly reported active cases for year by method of discovery (source of referral), such as chest X-ray surveys, tuberculin tests, contact examination, health examination, and self-referral.
3. Newly reported active cases for year by age, sex, race, marital status, geographic location of residence, occupation, and economic status.
4. Newly reported active cases for year by form and extent of disease.

2. Analysis of tuberculosis casefinding through tuberculin testing, based on the number of reactors rather than on persons tested, showing yield by age, sex, and race; also by length of time from discovery of infection to emergence of disease.

3. Comparison of stage of disease of new active cases found in tuberculin testing programs with those found by chest X-ray surveys of similar groups of persons.

4. Comparative cost of finding active cases by tuberculin testing surveys and by chest X-ray surveys.

5. Nontuberculous disease found in tuberculosis casefinding programs.

6. Completeness of case reporting.

7. For deaths in a specified time period, time intervals between date of morbidity report and date of death.

8. Extent to which known active unhospitalized patients are following treatment recommended.

9. Disease reactivations.

10. Hospital admissions and discharges within a given time period:

(a) Average length of stay as related to diagnosis on discharge, age, and sex.

(b) Admission diagnosis compared with discharge diagnosis as related to length of stay and other factors.

(c) Length of time between hospital discharge date and receipt of referral by the health department.

11. Analysis of social factors which have contributed to nonacceptance of medical recommendations by patients with tuberculosis, and the extent to which resolution of social problems has led to an acceptance of treatment.

12. Extent to which patients who received social service had their problems resolved compared with those who did not receive social service, with analysis of reasons for nonresolution in both categories.

13. Analysis of other than social factors which have contributed to nonacceptance of medical recommendations.

Training in Epidemiology

A course in applied epidemiology will be offered at the Communicable Disease Center, Public Health Service, Atlanta, Ga., May 4-8, 1959.

This course is designed primarily for physicians who investigate disease outbreaks or who have administrative responsibility for such investigations. It serves as a review for experienced health administrators and as a guide to physicians new to the public health field.

Emphasis is placed on developing an understanding of the use of epidemiological techniques to solve preventable disease problems. Lecture-discussion sessions and audiovisual aids are used in the presentations. Group participation is stressed through group solution of epidemiological problems, seminars, and panel discussions.

Further information and application forms may be obtained from: Chief, Communicable Disease Center, Public Health Service, 50 Seventh Street NE., Atlanta 23, Ga. Attention: Chief, Training Branch.

(a) Report of medical examination (X-ray or clinical) not overdue.

(b) Report of medical examination overdue:
(i) last examined less than 12 months ago;
(ii) last examined more than 12 months ago.

4. Bacteriological status of active and probably active cases not hospitalized.

(a) Positive at last report within past 6 months.

(b) Negative at last report within past 6 months.

(c) Status undetermined in past 6 months.

5. Unhospitalized cases with drug therapy currently prescribed, by clinical status.

CASE SUPERVISION: NURSING SERVICES

1. Of unhospitalized tuberculosis cases at a specified time, number not visited (home, office, or clinic) by public health nurse within preceding 6 months, by clinical and bacteriological status.

2. Of new active cases reported during year, number visited (home, office, or clinic) by public health nurse within 1 month of date of official morbidity report.

3. Of cases discharged from hospitals during year, number visited (home, office, or clinic) by public health nurse within 1 month of discharge, by clinical status (excluding deaths, transfers, nontuberculosis cases, and persons hospitalized only for diagnosis).

4. Total number of visits (home, office, or clinic) to all tuberculosis patients during year, by purpose of visit (guidance or instruction, therapeutic care, collateral service).

OTHER NURSING SERVICES

Total number of suspects, contacts, and associates of reactors who receive public health nursing service during year.

TUBERCULOSIS HOSPITAL DATA

1. Percentage of available tuberculosis beds occupied as of a specified date.

2. Average cost per patient day.

3. Average length of stay.

4. Number of patients discharged from tuberculosis hospitals during year (excluding transfers, nontuberculous cases, and persons hospitalized only for diagnosis) by

(a) Clinical status and type of discharge.

(b) Clinical status and bacteriological status.

(c) Recommended treatment: drug therapy only; rest only; both drug therapy and rest.

MEDICAL SOCIAL SERVICE

1. Number of active tuberculosis patients in current caseload referred to social service during a specified period.

2. Number of these patients served by medical social workers by end of specified period, either through direct service (casework or consultation) to the individual patient or indirectly through interagency activities.

VOCATIONAL REHABILITATION

- Number of tuberculosis patients referred by health department for vocational rehabilitation to both official and voluntary agencies during year: (a) accepted for rehabilitation; (b) not accepted (either agency or patient nonacceptance); (c) acceptance pending.

SPECIFIC PREVENTION

1. Number of BCG vaccinations administered during year to (a) persons in families with tuberculosis, by age and race; (b) persons in other groups (nurses and medical students, for example), by age and race.

2. Number of persons receiving chemoprophylaxis as of a specified date, by age and race.

EDUCATION AND TRAINING

1. Types of inservice training for public health professional workers and others.

2. Types and number of training sessions for volunteer workers.

3. Number of contacts with and presentations to organized civic and service groups.

Special Studies

Where a sustained program is well developed and additional statistical information can be utilized, greater attention can be given to special phases of tuberculosis control activities. Studies can be undertaken to develop more definitive statistical information and to provide greater refinement in measurement. The following are suggested as special study topics:

1. Prevalence of tuberculin sensitivity among adults.

viruses. Serums from 103 chickens in 3 flocks on the outskirts of the city were tested.

The second survey, conducted in January 1957, was designed as an indicator of immunity levels among the human population. Serum specimens were obtained from a total of 340 volunteers representing all age groups, all parts of town, and all economic classes. The specimens were then tested for the presence of complement-fixing antibodies against the SLE virus by the Virus and Rickettsia Laboratory of the Communicable Disease Center, Public Health Service. One hundred of these specimens, selected to give equal distribution among the different age and sex groups, were tested for HAI antibodies against both SLE and WEE viruses. Also, 96 of the 100 were tested for neutralizing antibodies against SLE. Antibody levels were classified as significant, equivocal, or insignificant by use of the following criteria:

Classification	HAI	Test SN ¹	CF
Insignificant.....	<1:10	0-32	<1:2
Equivocal.....	1:10	33-50	1:2
Significant.....	>1:10	>50	>1:2

¹ Neutralization Index.

There were no attempts at virus isolation from mosquitoes nor was the predominant mosquito species identified, the reason being that cold weather had brought about an end to the mosquito season by the time the investigation began.

Epidemiological investigations revealed that the outbreak of human cases apparently began on July 28 when a farmer from Fruita, 10 miles west of Grand Junction, became ill with symptoms of fever, severe headache, stiff neck, nausea, malaise, weakness, generalized muscle pain, and hand tremor. On July 29 he was hospitalized. The same day, a 3-year-old girl in Grand Junction became ill with similar symptoms. From that point the cases increased in number until October 15. By that time 31 cases had been seen by physicians in Grand Junction and Fruita. Thirty of these were among residents of Grand Junction.

The peak of the epidemic curve was reached in late August, and a secondary rise occurred during the first 2 weeks of November as 3 more

cases of encephalitis were reported. The etiology of these last three is unknown. Serologically they were not arthropod-borne encephalitis.

All age groups were affected, with the largest number of cases (seven) in the group from 20 to 29 years of age (table 1). Clinical illness was almost equally divided between males and females.

Serum was collected from 20 of the 31 patients through which the illness of 3 of these 20, or 15 percent, was confirmed serologically as SLE. An additional 13 cases, or 65 percent, were classified as serologically suggestive of SLE. Attempts to demonstrate antibodies against the common encephalitides (SLE, western equine encephalitis, eastern equine encephalitis, lymphocytic choriomeningitis, and mumps) all failed in serum samples from the remaining four, or 20 percent, of the cases.

Table 1. Comparison of the age distribution of clinical cases of encephalitis with that of the population which had measurable antibody levels against the SLE virus, Grand Junction, Colo., 1956

Age groups (in years)	Clinical cases		Survey		
	Num- ber of cases	Percent of cases	Percent with CF anti- bodies	Percent with HAI anti- bodies	Percent with neutral- izing anti- bodies
0-9.....	3	9.7	1.8	20.0	20.0
10-19.....	4	12.9	4.4	20.0	22.2
20-29.....	7	22.6	4.0	0	15.0
30-39.....	6	19.3	0	0	21.1
40-49.....	3	9.7	0	0	0
50-59.....	2	6.5	9.1	20.0	20.0
60 and over..	6	19.3	4.8	0	0
Total.....	31	100.0	2.9	5.0	16.7

The serum surveys showed that 1 percent of the 100 humans and of the 103 chickens surveyed had significant antibody levels against WEE. In contrast, 16.5 percent of the chickens and 0 to 12.5 percent of the humans, depending upon the test used, had significant antibody levels against the SLE virus (table 2). The percentage of each human age group with antibodies against the SLE virus can be

St. Louis Encephalitis Outbreak During 1956 In Grand Junction, Colo.

LUTHER E. GIDDINGS, M.D., LEE W. SMITH, M.S.,
MARGARET E. N. BEAVER, M.D., and CLARENCE A.
SOOTER, Ph.D.

THE FIRST sizable outbreak of St. Louis encephalitis among humans in the Rocky Mountain area occurred in 1956 in Grand Junction, Colo., and the surrounding valley on the western slope of the mountain range.

The area had experienced only scattered cases of St. Louis encephalitis since the disease was first recognized in St. Louis in 1933 (1). The midwest and the Pacific coast, however, had had occasional outbreaks and frequent sporadic cases of both St. Louis encephalitis and western equine encephalitis, two of the three arthropod-borne encephalitides which are found in this country. Eastern Colorado, with its dry, rolling plains, falls into the midwestern epidemiological pattern, but little is known about the natural occurrence of St. Louis encephalitis and western equine encephalitis in the mountains, canyons, and valleys of western Colorado, in which Grand Junction lies.

A city of 18,500 people, Grand Junction is at the junction of the Colorado and Gunnison Rivers in Grand Valley, which spreads over 15 by 30 miles at about 4,500 feet above sea level. The valley is encircled on three sides by pla-

teau and bordered on the fourth by desert. Numerous canals, irrigation ditches, and small swampy patches along the borders of the river contribute to the city's mosquito-breeding potential.

The outbreak of 1956, which occurred farther above sea level than any previously reported, was part of a statewide rise in activity of the St. Louis encephalitis (SLE) virus. Thirty-one cases of encephalitis were reported from Grand Junction and from the surrounding parts of Mesa County. There were no fatalities.

Epidemiological Methods

As each case of encephalitis occurred it was reported to the Mesa County Health Department by a private physician. Epidemiological information was then collected on each patient by a physician-epidemiologist or by a public health nurse from the department.

Attempts were made to collect an acute-phase serum specimen soon after the onset of the disease. Convalescent-phase serum specimens were generally collected between 3 and 8 weeks later. All paired serum specimens were tested with the serum neutralization (SN) test, the complement fixation (CF) test, and the hemagglutination-inhibition (HAI) test for antibodies against the SLE and western equine encephalitis (WEE) viruses. Single convalescent-phase specimens were tested with the HAI test only.

A case was classified as "confirmed" if a fourfold rise in titer was obtained with the CF or HAI tests or if a tenfold rise in neutralization index could be demonstrated. A case was classified as "suggestive" if the illness was clinically compatible with the disease and a CF titer of at least 1:8 or an HAI titer of at least 1:80 could be demonstrated in either a single convalescent-phase specimen or in paired specimens where a rise in titer was not demonstrable.

After the outbreak of human encephalitis had run its course still more information was desired. Accordingly, two serologic surveys were performed. The first was conducted in November 1956 among yearling chickens for HAI antibodies against the SLE and WEE

At the time of the study, Dr. Giddings and Mr. Smith were with the Encephalitis Investigations Unit, Greeley Field Station, Communicable Disease Center, Public Health Service, Greeley, Colo. Dr. Giddings is currently a resident in pediatrics at Salt Lake County General Hospital, Salt Lake City, Utah, and Mr. Smith is with the Graduate School of Public Health of the University of Pittsburgh. Dr. Sooter continues serving with the Encephalitis Investigations Unit of Greeley Field Station. Dr. Beaver is director of the Mesa County Department of Public Health, Grand Junction, Colo.

as many specimens were used in the CF test as in either of the others. CF results from those serum specimens which also were tested with the HAI and SN tests appear much closer to results of the three tests in age distribution of inapparent infection. However, to omit CF results from the remaining 240 samples would be to sacrifice accuracy unnecessarily.

An explanation for the low level of inapparent infection during the 1956 outbreak of clinical encephalitis has not been found. None of the 340 serums tested had a CF titer greater than 1:2. A control serum from a girl who had clinical SLE in August 1956, when tested, unidentified, with the other samples had CF antibodies at a titer of 1:64. It can be assumed from this that recent inapparent infection, had it occurred, would have been obvious from results of the CF test. The fact that inapparent infection is not greatest in age groups with the largest number of clinical cases also makes it appear that the cases of inapparent infection probably occurred sometime prior to the 1956 outbreak.

HAI results show that there was more SLE activity than WEE activity in Grand Junction in 1956. The fact that 16 times as many yearling chickens and 3 times as many humans had HAI antibodies against SLE would be indicative of this. Evidence exists that the virus of SLE was also more active than that of WEE in other parts of Colorado in 1956. Not only was the SLE virus isolated much more frequently from pools of *Culex tarsalis* mosquitoes in Weld County in eastern Colorado, but scattered cases of SLE were reported among humans along the east slope of the mountains and on the eastern plains where no cases of WEE were confirmed.

Summary

An outbreak of encephalitis among humans in Grand Junction, Colo., and the surrounding

valley during 1956, part of a statewide increase in activity of the St. Louis encephalitis virus, was the first outbreak of the disease in the Rocky Mountain area.

Thirty-one cases, with no fatalities, were reported in the outbreak, which occurred farther above sea level than any previously reported.

In a serologic survey of 340 persons, it was found that 16.7 percent had neutralizing antibodies against SLE.

A serologic survey of yearling chickens showed that the SLE virus was far more active than the western equine encephalitis virus in Grand Junction in 1956.

Differences in results from the complement fixation, hemagglutination-inhibition, and serum neutralization tests evolved from the use of different sample sizes in each test and from variations in the life of the antibodies sought in each test.

Human	SN	96	80	83.3	4	4.2	12	12.5
Chicken	HA1	103	84	81.6	2	1.9	17	16.5

compared with the age distribution of the clinical cases in table 1.

Discussion

The epidemic curve and age distribution of the outbreak roughly paralleled those in the original outbreak of SLE in St. Louis, Mo., in 1933 and in a more recent outbreak in the Rio Grande Valley in Texas in 1954 (3). In each, the epidemic curve started upward in late July or early August, reached a peak in late August, and then declined through September and October, and in each outbreak the majority of the cases were in the middle and older age groups. The attack rate in the Grand Junction outbreak of 162.3 per 100,000 compares with that of the original outbreak in St. Louis of 100 per 100,000 and the more recent Texas outbreak, 163.9 per 100,000, but is far below that in Calvert City, Ky., in 1955 in which the attack rate was 865.6 per 100,000.

In the light of an expected mortality of 5 to 30 percent from SLE (4), the fact that none of the 31 patients died is unusual. Observations by some workers have shown that SLE in humans is usually somewhat milder in the west than in the midwest. These workers postulate that the reason for this is the presence of a strain of SLE virus in the west which is less pathogenic for man than the midwestern strains (personal communication from Dr. Carl M. Eklund).

Approximately 12.5 percent of the population tested for previous inapparent infection had neutralizing antibodies against the SLE virus at a significant level. This is comparable with the 11.8 percent found in Weld County in north-

eastern Colorado in 1951 (5). In the Weld County survey few under the age of 20 years had significant antibody levels, whereas in Grand Junction nearly half of those with antibodies were less than 20 years of age. There are a number of possible explanations.

The marked differences in the serologic survey results according to the test used were due partially to the fact that neutralizing antibodies against the SLE virus persist for a considerable length of time, possibly more than 10 years, while CF antibodies persist only for a period of several years (6). HA1 antibodies are thought to have a duration somewhere between those of the other two. Consequently, when all three tests are run, it is possible to obtain some indication of the activity of the SLE virus in a given area over a period of possibly 10 years. Accordingly, survey results in table 1 might be interpreted thus: the SLE virus was moderately active in humans in the years 1954-56 since 2.9 percent of the population have CF antibodies. A larger number, 5.0 percent, have HA1 antibodies so it is likely that the virus was also moderately active in the years 1951-53. Since a still larger number, 16.7 percent, have neutralizing antibodies, it can be assumed that this moderate level of activity goes back beyond 5 years, possibly as far back as 10 years. It must be realized, however, that a single year with heavy activity between 1946 and 1951 could bring about the difference in results between the serum neutralization test and the other two tests. There is no record of such activity having occurred prior to 1956.

Another reason for the differences in survey results is that samples of different sizes were used in the three tests. More than three times

A total of 135 medical, dental, engineering, science, nursing, and veterinary students from 120 approved 4-year professional schools spent the summer months of 1958 in Public Health Service facilities under the Service's training program.

Signs

and

Symptoms

of trends in public health

Colorado's 54,000 old-age pensioners are guaranteed \$100 a month income, and are permitted to go to any hospital and receive the same treatment as regular patients at State expense.

If the aged person cannot live alone, he goes to a convalescent or nursing home, and contributes all but \$5 of his monthly income; the State pays the balance. A sum of \$10 million has been set as the annual allocation to finance the program; Blue Cross and Blue Shield administer it. State officials believe that revenues earmarked for pensions will exceed the cost of the program.

EVALUATION OF A MOUSE TEST FOR THE STANDARDIZATION OF THE IMMUNIZING POWER OF ANTI-RABIES VACCINES¹

By KARL HABEL, Assistant Surgeon, United States Public Health Service

The ideal animal test for the standardization of any vaccine should be done under conditions either similar to or at least comparable to those under which the vaccine is used clinically in human beings. The technique of performing the test should be simple and there should be no procedure in which individual differences of the technician might cause variation in results. The time required to complete a test is of practical importance since the material being tested cannot be released for clinical use until successfully meeting the requirements. Therefore the duration of the test should be sufficiently short so as not to subtract materially from the life of the vaccine.

Results should be unequivocal and subject to but one interpretation. On repetition of identical tests the results should be uniform. The test animals used should be easily available, inexpensive, and easily cared for in the laboratory. The material used in testing the immunity produced by the vaccine must be uniform; its potency, its potency, or the test must be so arranged that any changes in these properties will be revealed in the results. These are the requirements of the ideal test.

Since rabies vaccine was first used it has been subjected to many types of experimental tests to determine its immunizing properties and, therefore, its efficacy in the Pasteur treatment of human beings. This subject has been reviewed recently by Webster (1), who emphasizes the general lack of positive results in the light of statistical analysis of the published protocols.

In general, the following types of tests have been used.

1. *Injection of rabies virus into central nervous system (subdural, intracerebral, intraocular) followed by a course of vaccine treatment (1).*— In this method results have been quite consistently negative, the same mortality usually occurring among the vaccinated and control animals. This is easily understandable, since the direct introduction

Dr. Karl Habel in this classic mouse protection test establishes for an efficient rabies vaccine the minimum requirement of protection against at least 1,000 MLD (minimum lethal dose).

RESIDUAL FUMIGANTS

Their Potential in Malaria Eradication

WILLIS MATHIS, B.S., RICHARD W. FAY, Ph.D.,
H. F. SCHOOF, Ph.D., and K. D. QUARTERMAN, M.P.H.

RESIDUAL fumigants offer a new technique of vector control which is potentially capable of revolutionizing the insecticidal approach to malaria eradication.

Current malaria eradication programs depend primarily on interrupting the transmission of the disease through the use of residual insecticides, chiefly DDT and dieldrin. Although considerable success has been achieved with this method during the past decade, similar accomplishment in some areas is being hampered by (a) development of vector populations resistant to these insecticides, (b) variation in the efficacy of residues caused by the type of surface to which they are applied, (c) destruction or removal of the insecticidal deposits by replastering, washing, or other modifications of the treated surfaces, and (d) variation in the behavior of the mosquitoes. Consequently, a method which would reduce or eliminate the influence of any of these factors would hasten the achievement of the ultimate goal of global malaria eradication.

The authors are with the Technical Development Laboratories of the Communicable Disease Center, Public Health Service, in Savannah, Ga. Mr. Mathis is a medical entomologist, Dr. Fay is assistant chief, and Dr. Schoof is chief of the Biology Section. Mr. Quartermann is chief of the laboratories. (Manuscript received for publication March 23, 1959.)

That certain toxicants, such as lindane, DDVP, Diazinon, and malathion, possess fumigant properties is an established fact. Moreover, in recent studies of the effectiveness against *Anopheles quadrimaculatus* of malathion deposits on walls, it was noted that 75 to 100 percent of the mosquitoes remaining in the entrance cages attached to the outside of the animal-baited huts were killed (1).

The death of these mosquitoes was presumed to result from malathion vapor being carried to the entrance cages from the interior of the huts by air currents. The magnitude of the fumigant action of organophosphorus compounds against mosquitoes was first detected accidentally through the unexpected mortality of mosquitoes in use as "check" insects in laboratory tests. Apparently, they were killed by fumes from an unopened bag of fly bait containing malathion and DDVP. To confirm this premise, two cages of *A. quadrimaculatus* were placed 1.5 and 3.5 feet above floor level in a small room (5 by 9 by 10 feet) at sites approximately 7 to 10 feet from the same unopened bag of bait located at floor level in an adjoining room (10 by 14 by 10 feet). The rooms were unoccupied and closed to the exterior, and the connecting door remained open. All specimens died within 2.5 hours. The fact that the unopened bag contained a plastic liner emphasized the mobility of the vapor.

To evaluate this fumigant action under less favorable conditions, the tests described below were conducted in an unoccupied two-room house and in two small huts.

House Test

Each room was 13 by 12 by 8 feet. One contained an exterior door and a window, and the other, two windows. All these and an interior door between the rooms were fully open. Cages of both susceptible *Aedes aegypti* (400 adults) and *Musca domestica* (200 adults) were placed in five positions in the two rooms as follows: room I-A, sheltered corner; room I-B, in open window; room I-C, above interconnecting door; room II-D, exposed corner; and room II-E, sheltered corner.

Four 5-pound bags of fly bait composed of 2.0 percent malathion and 0.5 percent DDVP were placed in room I on the floor, 5 to 8 feet from cage sites A, B, and C, and 13 and 17 feet respectively from sites D and E. The bait containers were double-paper bags lined with plastic. One was opened, and the others remained sealed. All specimens were exposed for 1 hour, during which time a gentle breeze (estimated 10 m.p.h.) passed through both rooms. After 24 hours, mortality for female houseflies was 21 to 24 percent at cage sites A, B, and C, and 2 and 0 percent at sites D and E. For female mosquitoes, the values were 95 to 99 percent at sites A, B, and C, and 64 and 52 percent at sites D and E.

Hut Tests

Each hut (8 by 8 by 8 feet) had 2 windows (3 by 3 feet) on opposite sides, both of which remained open during the entire experiment. In hut I, a single 5-pound open bag of bait containing 2 percent malathion and 0.5 percent DDVP was placed in the center of the floor; in hut II, three open 5-pound bags of the same bait were located one each at the apexes of a triangle (2 ft.) near the center of the floor. One hundred female *A. quadrimaculatus* were released in each hut at 3 p.m. 1 week after the baits were installed, and at weekly intervals during the next 3 weeks. The morning following each release, all specimens, both living and

dead, were collected and held for 24- and 48-hour mortality determinations. Results showed 100 percent mortality for each of the four weekly tests in each hut. The tests were discontinued after the fourth week.

During the fourth week, caged specimens (25 females per cage) were exposed for the same time interval at floor level, and at 2, 4, and 6 feet above the floor. In hut I, all specimens at floor level and at 2 feet were dead within 48 hours. At the 4- and 6-foot levels, 44 and 88 percent respectively were killed. In hut II, mortality was 100 percent for all positions. However, mortality at floor level in an untreated check hut was also relatively high (24 percent).

Subsequent tests were made to determine whether malathion or DDVP, or the combination of the toxicants, was responsible for the residual toxicity. Separate formulations of 2 percent malathion plus 0.5 percent DDVP, of 0.5 percent DDVP, and of 2.0 percent malathion were prepared in a granular inorganic material (A). A 5-pound lot of each formulation was bagged in a paper container, and the bag was left open and placed in the center of the hut floor. Both "free-flying" and caged *A. quadrimaculatus* were introduced into each hut at 3 p.m., 3 hours after the bait was installed.

The following morning all mosquitoes, whether "free-flying" or caged, were dead. With the combination of malathion and DDVP and with DDVP alone, all the specimens were knocked down 3.5 hours after exposure began. With malathion alone, only a few specimens were down after 4.5 hours of exposure.

Tests on the residual potency of these formulations were precluded because of the onset of cold weather.

Discussion

The potential of residual fumigants for controlling house-frequenting adult mosquitoes, although obviously successful in producing a high mortality for 4 weeks, has not been explored fully in these preliminary tests. Further studies under laboratory and field conditions are now in progress to determine which toxicant or combination of toxicants is most effective, the

duration of residual action under various environmental conditions, efficient methods of formulation in small, lightweight units, and the toxicological hazards. The possibility of toxicological hazards to the occupants of treated dwellings represents a principal question concerning the practical use of the fumigants. This aspect will require extensive study before the technique can be put into general practice.

If the use of residual fumigants proves feasible, it is readily foreseeable that this technique could result in important monetary savings by simplifying malaria eradication operations. Manpower requirements would be reduced drastically; the need for spraying equipment, with its attendant burdens of maintenance, as well as problems currently encountered with wettable-powder formulations, would be minimized; and other difficulties associated with residual spraying, such as the sorption of residues by certain mud surfaces, objections to the unsightliness of residues on some walls, and the modifications of treated surfaces by replastering, washing, and the like,

would be eliminated. Although mosquitoes appear more susceptible to fumigant action than houseflies, the technique may be effective also against other types of house-frequenting insect vectors and pests.

Because of the many potential advantages which the residual fumigant technique may offer in malaria eradication and in the control of other mosquito-borne diseases, it is hoped that the encouraging results of these preliminary tests will stimulate other workers to investigate the many questions which must be answered before the technique may be adopted for general use.

Alaskan Research Advisory Committee

An Interagency Research Advisory Committee has been formed by representatives of the Alaska Department of Health, the U.S. Air Force Arctic Aeromedical Laboratory, and the Public Health Service's Alaska Native Health Service and Arctic Health Research Center. Its purpose is to assist scientific investigators in medical and allied fields who wish to perform research in Alaska.

The committee is prepared to aid investigators sponsored by a recognized institution by explaining local situations, helping solve logistic difficulties, and making available Alaskan facilities.

Persons desiring such assistance should write to E. M. Scott, Chairman, Interagency Research Advisory Committee, Arctic Health Research Center, Box 960, Anchorage, Alaska.

Live Attenuated Poliomyelitis Vaccine

For many years, the possible use of a live attenuated poliomyelitis vaccine, that is, a virus which has been grown in animals or eggs until it has lost its disease-producing potential without losing its immunizing ability, has been discussed. For more than 7 years, the problem has been under serious investigation.

The Salk vaccine, now in use and giving good results in protecting against paralytic poliomyelitis, is made from killed virus.

The main advantages visualized for a vaccine made from live attenuated virus are: (a) longer lasting immunity—although the Salk vaccine is believed to provide protection for some time, the actual duration of immunity is not yet known because it has been in use for such a short time; (b) ease of administration, with the live virus given orally instead of by injection; and (c) presumably lower costs of production.

At the present time three sets of strains are under investigation. These are most readily identified by the names of their developers, the Sabin, Lederle, and Koprowski strains, named respectively for Dr. Albert Sabin of the University of Cincinnati, Lederle Laboratories, and Dr. Hilary Koprowski of Wistar Institute of Philadelphia. The name of Dr. Herald Cox, of the Lederle Laboratories, is also associated with the Lederle strains.

Each set consists of three type strains. These sets of strains have now been administered to large numbers of persons in an attempt to determine: (a) their ability to produce adequate and durable levels of antibody, and (b) their safety in general use.

No untoward results have been

reported in relation to these studies. Stated in this way, the facts appear impressive. It must be remembered, however, that the data these studies were designed to collect have not yet been fully assembled, analyzed, or made public.

The Public Health Service is following these developments closely. Our Division of Biologics Standards of the National Institutes of Health, for example, is conducting laboratory investigations aimed at characterizing the type strains. These investigations are of importance because the Service may be asked some day to license the products.

I also have appointed an ad hoc committee composed of outstanding experts in this field to keep me advised of developments with respect to live attenuated poliomyelitis vaccines. This committee consists of Dr. Roderick Murray, chairman, director of the Division of Biologics Standards, National Institutes of Health; Dr. David Bodian, Johns Hopkins University; Dr. William McD. Hammon, University of Pittsburgh School of Public Health; Dr. Alexander Langmuir, Public Health Service, Communicable Disease Center, Atlanta, Ga.; Dr. Joseph Melnick, Baylor University, and Dr. John R. Paul, Yale University Medical School.

This committee has met twice and considered all information now available on these vaccines. The committee finds a number of important issues remain to be answered or resolved before the live attenuated poliomyelitis vaccines can be considered other than in the experimental stage.

These issues cover such points as: apparent differences in the ability of the different strains to invade the nervous systems of experimental ani-

mals; transmission of virus from vaccinated persons to others; feasibility of feeding the three type strains simultaneously; effect of viruses in the intestinal tract, other than polioviruses, on the development of immunity to poliomyelitis; validity of surveillance of populations inoculated to date.

The committee has felt some concern because some of the trials of live attenuated poliomyelitis vaccine have not followed the recommendations of the World Health Organization Expert Committee on Poliomyelitis. It also has been concerned by apparent differences in the virulence for the nervous system of some of the virus strains being used. This aspect of the problem needs further study.

The experience thus far indicates that encouragement should be given to carefully conducted, small-scale studies designed in such a way that the laboratory and epidemiological surveillance could produce results upon which a judgment could be made.

Large-scale trials of live attenuated poliomyelitis vaccine in the United States are considered unproductive because so large a proportion of the population already has been immunized with killed vaccine.

The decision to permit such trials in other nations is, of course, one for their health and medical authorities. However, because the experimental vaccines are made in the United States and because our ad hoc committee has been studying reports on them, I feel that such information as we have should be made public so that not only our people but the peoples of other nations can have all current available information as exists on which to form their opinions and base their decisions.

Homemaker Service in New Jersey

MARIAN R. STANFORD, M.D.

COMMUNITY homemaker service in New Jersey is a locally sponsored nonprofit activity to place women workers in households in which they are needed because of illness or disability or other family emergency. The placement of the worker is made by the local agency after evaluation of the home situation. The hours of service vary according to the family's need. Payment for the service is an obligation of the family or of a community agency if the family cannot afford to pay.

Homemakers are mature women selected for their personality, dependability, good health, and special interest in working with families in which there is a family crisis. After screening and acceptance by a local committee, they take a standardized 19-hour training course. Those who complete the course satisfactorily receive a certificate. The course is sponsored and financed by the New Jersey State Department of Health's division of chronic illness control and administered through the extension division of Rutgers, the State University. Upon acceptance for service by the agency, the homemakers are given physical examinations, including chest X-rays and blood tests. They receive cards indicating they are in good health and they wear standard uniforms. While employed, they are covered by workmen's compensation, public liability insurance, and social security. This is arranged by the sponsoring agency.

What Homemakers Do

Homemakers do light housekeeping. They are not expected to do a huge family wash nor the spring or fall housecleaning. Nor are they a new category of domestics to do cleaning.

Fundamentally, their task is to assist the members of the family in maintaining a smoothly running household. They may set the house in order by straightening up, dusting, washing the dishes, and keeping the patient's room clean and fresh. They may plan or actually do the marketing, depending on the availability of other personnel in the family. They may prepare meals for the family, including lunches for the children and the breadwinner. They also prepare meals for the patient with due regard to the instructions of the physician. (Some orientation to the special dietary needs of sick persons is given in the preliminary training course which is a prerequisite to employment.) Homemakers provide essential care for young children and encourage well members of the family to carry their share of responsibility.

Homemakers are specifically advised that they are not to do bedside nursing or other nursing duties. Thus they complement rather than substitute for or compete with a community visiting nurse or practical nurse service.

The homemaker develops on the job. She is periodically supervised on the job. She is required to report on each case and confer frequently with her supervisor. These reports and conferences provide evidence of her competence, her reaction to illness and family situations and to the work she is performing. She aids the agency in evaluating the needs of the family and the length of service required. Her observations often are helpful to the supervisor and the physician; physicians and families volunteer

Dr. Stanford is director of the division of chronic illness control, New Jersey State Department of Health, Trenton.

information to the agency about the homemaker's competence and performance.

Effects of the Service

Community homemaker service helps to prevent a breakdown in the orderly management of the household because of illness or other family emergency. It prevents inadequate supervision of children; poor family nutrition; disproportionate burdens on some members of the household which could produce fatigue, worry, anxiety, resentment, and hostility; loss of efficiency; absence from work of employed members of the household; and absence from school of older children. Physicians say the service has prevented temporary breakup of the household, removal of sick persons from familiar surroundings to institutions, and placement of children with relatives or in foster homes.

From the standpoint of the community, the homemaker service may free more hospital beds for the acutely ill, may decrease demand for custodial facilities, and may eliminate the cost of avoidable institutional care.

History of Development

The promotion of community homemaker service in New Jersey is an outgrowth of the State health department's interpretation of its responsibilities under the Prevention of Chronic Illness Act of 1952 (chapter 102, Public Laws of 1952). This State legislation established within the department a division of chronic illness control. The division was directed to assume responsibility for activities directed toward the prevention, early detection, and control of chronic illness and the rehabilitation of the chronically ill.

Section 26: 1A-97-b of the Prevention of Chronic Illness Act provides that the division shall "plan for the provision of adequate visiting nurse and housekeeping aid services by appropriate public or private agencies throughout the State, to the end that the nursing and medical care being furnished to the chronic sick in their own homes shall be improved in every manner possible."

It is not the function of the New Jersey State Department of Health to provide direct serv-

ices to the consumer; its function is to strengthen the community's capacity to provide such services. The division's effort helps to stimulate the development of community supportive services; the division does not directly provide that service through its own staff and personnel.

Prior to the creation of the State Consultant Committee on Community Homemaker Service, there were three homemaker services operating in New Jersey, two of them of the traditional type. These two were attached to family service agencies and provided help on a full-time basis to distressed families on the rolls of the agency, using an average of two homemakers in each agency.

In 1950, the third homemaker service, specifically planned to meet the needs of long-term patients, was started in Essex County under the sponsorship of the Essex County Medical Society. The primary objective was to lessen the emotional and financial toll of long-term illness by making it possible to care for the patient in his own home. Service was provided initially to the chronically ill. Later, homemaker service was provided to some persons with short-term illness, especially when it seemed likely that such help might prevent the illness from being prolonged.

The Essex County service served as a pattern for additional agencies. Recruiting homemakers from middle-aged and older women constituted a new approach. It provided satisfying work to a group which was otherwise finding it difficult to obtain employment in the labor market. The limited time basis on which the service is given, usually 2 to 6 hours per day, makes it particularly suitable for some women who might not feel physically capable of full-time employment.

In 1953, Dr. Daniel Bergsma, State commissioner of health, appointed the State Consultant Committee on Community Homemaker Service to promote the development of community homemaker services throughout the State. He asked the committee to develop a plan for community homemaker service specific enough to be used as a practical guide to interested communities but flexible enough to be adaptable to local conditions. He also asked it to develop a

Homemaker Films

"Home Again" was prepared for the New Jersey State Department of Health and the American Heart Association. It may be purchased from the Mental Health Film Board, Service Department, 267 West 25th Street, New York 1, N.Y. The price is \$145. Copies of the filmstrip "Enter Hope" are unavailable for distribution outside of New Jersey.

course of study to help women who seek such employment to become suitable homemakers. Members of this committee have included physicians, lawyers, nurses, nutritionists, social workers, teachers, persons trained in informational techniques, and persons with considerable experience in organizational work. The first chairman, who served for 4 years, was a member of the Temporary Committee on the Chronic Sick appointed by the Governor to study needs and recommend legislation. This committee drafted the Prevention of Chronic Illness Act.

The State consultant committee, which originally had 10 members, now has 40. The committee has subcommittees working on such areas of activity as intake criteria, procedures, resources, fees, insurance, publicity, and financial support. The department maintains membership with the National Committee on Homemaker Service.

A handbook, which presented a plan for community homemaker service, was one of the first projects and was published by the State department of health. It has received wide circulation. Another pamphlet is entitled "A Training Course in Homemaker Service." Shorter, descriptive, promotional brochures were also developed for distribution among potential users of the services.

A statewide institute and, subsequently, regional institutes on homemaker service acquainted community leaders with the service and how it operates.

As a result of conferences between the division of chronic illness control, its consultant committee, and officials of the New Jersey State Department of Banking and Insurance, a special category of "homemaker" was set up by

the banking and insurance department, enabling insurance carriers to charge an equitable rate which is adjusted each year on the basis of claims.

The division of chronic illness control and its consultant committee explored with the New Jersey State Department of Labor and Industry the status of the volunteer agency under employment laws in the event a small fee for administration was added to the hourly rate paid to the homemaker herself. (The hourly rate to the homemaker is usually \$1.25.) The New Jersey State Department of Labor and Industry concluded that the community homemaker service, as a voluntary nonprofit group, was exempt from regulations which apply to commercial employment agencies, provided the agency files the proper exemption forms.

Promotional Aids

Promotional aids, in addition to printed material, include a color filmstrip with sound recording and a 30-minute film. The filmstrip, entitled "Enter Hope," is a true story in pictures of community homemaker services in New Jersey. It shows the training homemakers receive, the kinds of service they give, and the benefits that accrue to the patient, the aged person, and the family group.

The film "Home Again" reveals the valiant efforts of a father to keep his family together when the mother is in the hospital because of a heart attack. For the first time in an American film, the role of the homemaker service is dramatized. The film also demonstrates how homemaker service by a supervised team approach can keep a family together in time of crisis and how it can help relieve emotional tensions and stresses and strains that impede recovery of the chronically ill.

Members of the State consultant committee, through their widespread and influential contacts, have inspired and helped to arrange local meetings on community homemaker service, and have spoken at many of them. The division of chronic illness control of the State department of health has fostered the program by underwriting the cost of the homemaker training course administered by Rutgers University. The division provides temporary grants-in-aid

National Homemaker Conference

About 300 persons attended the National Conference on Homemaker Services held February 10-11, 1959, in Chicago.

The conference was called to encourage development of programs to help families maintain themselves at home when illness or other major crises occur. Sponsored by 26 national voluntary agencies and 8 units of the Department of Health, Education, and Welfare, it was described as the most representative conference on homemaker services ever held in this country. About one-half of the participants had attended preconference study groups in New York City, Chicago, San Francisco, Cleveland, Raleigh, Denver, and Trenton.

The concept that homemaker services should be available to any family or individual on the basis of need, regardless of income or age, was set forth.

Agreement was reached that if homemaker services are to be extended nationwide, a partnership of agencies at Federal, State, and local levels is required.

Dr. David E. Price, chief, Bureau of State Services, and Assistant Surgeon General of the Public Health Service, in an address on the health-welfare partnership, said, "The mutual interest of the health

and welfare professions in extending homemaker services affords a good illustration of how closely health change and social change bind us in an inextricable partnership. The longer lifespan, a health gain, has given us an older population with consequent increase in chronic ills. These long-term disabilities in turn bring economic and emotional problems which can lead to more physical illness. Smaller families, working wives, and the change to an urban, apartment civilization—a social change—often give us no one to care for the bedridden and homebound. And so it goes, round and round, health-welfare, welfare-health. In the middle stands the homemaker, a personification of our partnership."

Dr. Price summarized, "I have noted a growing trend in health departments toward a research approach to public health practice. We are encouraging this in every way possible. At the State and local level, fresh ways of meeting health needs are being sought, trying to fit methods to people, rather than forcing people into rigid patterns of established procedure. In such a search, homemaker services should prove of interest to many."

in some instances to enable community homemaker services to acquire either part-time or full-time directors to strengthen supervision of the service in the home or to demonstrate countywide coverage and underwrites the cost of educational materials, training aids, and State conferences.

The training course for homemakers, given in various municipalities to make it more convenient for women to attend, includes consideration of these topics: what homemaker service is; working with people; homemaker and family relationships; accident prevention and safety in the home; family life in relation to food and home care; understanding children, the elderly, and mental illness; understanding

what occupational therapy is; and agency procedures.

There are now 12 established homemaker services in New Jersey, and more than 600 women have been trained as homemakers since June 1954. Most of the services are working toward a county service. Activity in four other counties gives promise of favorable development. From a population standpoint, more than half of the residents of New Jersey now have established homemaker services available to them. Geographically, more than one-third of the State is thus served. One objective of the health department and of its State consultant committee is to have such a service available to all families in New Jersey who need it.

LITTER

and the Public Health

HOMER N. CALVER, B.S.

THE FIRST street cleaning department in America was established in Philadelphia in 1750 by Benjamin Franklin, according to the American Public Health Association. Some 200 years later, in 1953, Keep America Beautiful was incorporated in New York City; it is the first national organization specifically set up to combat litter.

The growing litter menace had for some time been the concern of many kinds of national and local, official and voluntary organizations. Several of them were already valiantly fighting uncoordinated uphill battles to clean up our highways, streets, streams, parks, lakes, and beaches. These individual efforts brought temporary improvement here and there, but Keep America Beautiful undertook to wage continuous warfare on a national scale, emphasizing a new concept: the concept of prevention. This approach to the problem was designed to reduce the litter and therefore the enormous cost of cleanup and collection. It may be expected to produce more lasting results.

Mr. Calver, one of the founders of Keep America Beautiful, Inc., and former secretary of the American Public Health Association, is a consultant in public health and public relations in New York City.

The campaign against litter is a campaign against soil and water pollution. Early public health programs against indiscriminate pollution of soil and water with body wastes first emphasized the need for collection of these wastes (privies). Later, public health workers became concerned with transportation (sewerage). Refuse disposal was in general tackled in reverse order. Only lately have their efforts focused on the problem of getting the refuse properly accumulated in the first place. Litter might be defined as unaccumulated refuse, so the campaign against litter is in effect a campaign for the accumulation of rubbish at central points from which it may be more economically collected for transportation and disposal.

When environments are untidy, the health department is usually blamed, even though policing the environment may not be its responsibility. Every health department must therefore concern itself with the prevention of litter if for no other reason than to win public support for its whole program. In addition, however, public health workers have a direct stake in litter prevention as a way of reducing disease and accidents.

Rubbish promotes the breeding of rats, flies, and mosquitoes. It causes accidents, particu-

larly on highways. Cars swerve to avoid rubbish. Tires are cut, causing blowouts. Paper blows against windshields, obscuring vision at a critical moment. Reflections at night from a piece of glass or metal may be confused with the reflection from a traffic marker or mistaken for the eye of an animal. In the *Milwaukee Journal* of December 8, 1957, the Associated Press reported an estimate of 750 to 1,000 persons killed and 100,000 injured each year as a result of striking or swerving to avoid objects on highways. Refuse on beaches, in lakes and streams, in swimming pools, and in parks and playgrounds can cause cuts and abrasions which sometimes result in serious infections, and refuse on sidewalks and steps causes falls. Uncollected rubbish is the source of many fires, some of which cause injury and death. Litter in a lake or river can puncture the hull of a boat traveling at high speed, or damage a rudder or propeller. Such accidents can be the precursor of death.

There are also other attributes of litter. Dr. Justin M. Andrews, at the third annual conference of the Keep America Beautiful Advisory Committee in New York City in 1956, pointed out that "litter is frequently the surface symptom of a diseased environment." When the sanitarian sees this symptom he must be as concerned about seeking and removing the cause as the physician is about seeking the cause of a rash on the body. Here one might ask, what is the cause of litter? Is there an epidemiology of litter?

Without doubt, one cause of litter is mass production which makes it cheaper to discard and replace than to repair or re-use many things. Other causes are modern sanitary packaging, increased leisure time, increased mobility, and a food supply so abundant that we can waste much food. It is a wry thought that many of the attributes of a higher level of consumption are the very things which are impairing our health and the esthetic quality of our environment.

But there are additional causes. Some of the obvious ones are the lack of adequate trash receptacles at convenient points and infrequent and careless collections. But perhaps there are deeper causes as well. There would seem to be

some evidence that littering is communicable. For example, a beach, park, or highway which is already littered invites more litter. If some members of a family are in the habit of littering, other members of the same family are likely to have the same habits. There is more litter in some communities than in others. There are probably social, economic, regional, sex, and age factors related to litter production, just as there are surely seasonal variations in the amount of litter produced. These variables need to be identified. Pin maps showing pounds or bushels of litter per capita by areas might be illuminating in a study of the epidemiology of litter.

It is not sufficient to assume that general programs of education, publicity, and propaganda, or appeals to pride and pocketbook, or stricter laws better enforced will prevent litter over the long run. With litter, as with any other public health hazard, we cannot plan and focus programs of prevention until we have more information than we have now as to its causative factors.

The public health profession is uniquely equipped to solve some of the basic questions. Meantime it will have to deal with the problem of litter by empirical methods of law enforcement and education, just as it had to deal with yellow fever, cholera, and typhoid fever before the causes and routes of infection of these diseases were known. In this case, however, it is doubtful that an anti-litter serum can be developed or that if it were developed it would be used by the family physician.

Although the challenge is formidable, empirical methods are already producing remarkable results in many localities.

Philadelphia

In Philadelphia, for example, the junior sanitation unit has given new life to the Philadelphia Clean-Up Committee. The committee's block organization plan had met with little success until the boys and girls were formed into units in the schools by the city's police sanitation officers. Each member pledges to keep himself clean at all times and to aid in keeping his home, school grounds, and neigh-

New York Times photograph

Litter and rubbish in a 20-by-100-foot lot in Brooklyn presented not only an eyesore but a fire and safety hazard to the neighborhood.

neighborhood neat and litter free. Saturday mornings as their neighbors watch, the junior sanitation "cleaner-uppers"—who are easily identified by their white caps lettered "clean up"—work with verve and pride. Their contribution is not only material but inspirational as it stirs parents and neighbors to join in the crusade.

Today, Philadelphia has more than 975 organized blocks where flowers bloom in doorway and backyard gardens, in porch boxes and fence boxes, and even in sidewalk boxes—concrete troughs set against the houses and planted with climbing roses to brighten the once shabby streets. Block captains, a new aristocracy of citizens, work seriously, diligently, and enthusiastically with their groups, sparked with the contagious zeal of youth. The junior sanitation unit will also prove to be a reservoir of future leadership in the anti-litter movement.

Savannah

Savannah, Ga., started with a women's committee; a caricature of "Pelican Pete," a bird indigenous to the Georgian coast that could be used as a symbol to speak for the committee; and 30,000 litterbags which had been donated by a paper corporation. The slogan was Keep Beautiful Savannah Clean.

The litterbags created enough interest so that when trash receptacles in which to place them

New York Times photograph

The lot became a garden of flowers, shrubs, and vegetables, with a 10-foot maple tree, after transformation by school children.

after use were needed, individuals and business firms contributed them willingly. Window stickers of Pelican Pete were distributed, and 10,000 automobile stickers were given out by gas stations and banks. Silver cups were awarded to schools where the grounds were improved. So dedicated were boys and girls in the cleanup movement that mothers who became anti-litter committee members testified at meetings that no longer would they dare to throw trash from car windows lest they incur junior's censure.

Enlisting aid from all sources—civic, service, and fraternal organizations, and business and industry—the committee also appeared before the city council, county commissioners, police department, and health and sanitation department to ask their cooperation. Their efforts have brought about ordinance changes as well as all-out support of the community's continuing anti-litter program.

Indianapolis

"Yard Parks," Indianapolis' title for the year-round litter control program, is structured in special divisions with a "trouble-shooter" for each to investigate public complaints and take proper action. The divisions, such as allied florists, drug stores, and public health, make Yard Parks an integral part of all community activities, enlisting the support of every citizen

through his work, organization membership, or hobbies.

Litter prevention is being taught as the "yards beautiful" course in all public, parochial, and private schools in the city and county with full support of the educational phase by community groups and PTA units.

San Antonio

San Antonio, Tex., long famed throughout the country for its palm-lined avenues of lovely homes and artistically landscaped parks, deteriorated during World War II into a ghost of its former beauty. Littered streets, run-down houses with unkempt lawns, weed-grown lots, and neglected parks where plants and shrubs had been allowed to die had changed the face of the city.

Littering had become communicable. Lack of civic pride and indifference were deeply entrenched in the public consciousness. No civic group came forward. One man, O. P. Schnabel, spearheaded the movement to check littering. With very little support he called on the newspapers, radio, and television stations to arouse the citizenry. Some financial help came from business firms aware of the potential value of a clean city.

Throughout San Antonio were heaps of accumulated household trash. As no regular trash removal was made by the city, Mr. Schnabel and his committee initiated an annual trash haul. Private firms donated a truck and helpers, and in the first year, 1949, thousands of tons of trash were removed from homes and yards. These annual hauls not only saved citizens a million dollars in private trash-toting fees, but awakened them to the realization that their town was depreciating. More residents joined the campaign, and in 1951 San Antonio won its first National Cleanest Town Award in a contest sponsored by the National Clean Up, Paint Up, Fix Up Bureau in Washington, D.C. Since then, San Antonio has won an award every year, receiving the National Grand Award in 1954.

Today there is a Beautify San Antonio Association which cooperates with the chamber of commerce and other public and civic organiza-

Dunsmuir News photograph

Littered shoreline blights a beauty spot along California's McCloud River. Thousands of youth and adult groups have joined the movement to enhance and preserve the Nation's scenic beauty.

tions. More than 750 trash cans have been placed at strategic locations to encourage citizens to keep streets and parks clean. Elementary and high school students have conducted essay and poster contests and devised school checklists which have resulted in cleaner school grounds. Homes have been beautified through pressure exerted by children upon their parents. The city health department regularly notifies owners of unkempt lots. If the owners fail to respond, the department cleans up the debris and bills them for the cost.

As a long-range plan for making America litter free, officials of the Beautify San Antonio program advocate that future automobiles should have built-in trash receptacles. They believe that 90 percent of Americans will cooperate if they have a place to deposit litter while driving. Meantime, they are encouraging the use of disposable litterbags and other portable containers.

Four-Point Formula

These four cities are not unique. Each became aware that it was faced with a problem, and met the situation as it best suited the individuality and resources of the community. These and other cities, currently dedicated to the fight against litter, are finding effective the four-point formula for litter prevention of Keep America Beautiful. It includes:

- Public education to cultivate individual responsibility, civic pride, and good citizenship habits.
- Participation in public interest projects for cleaner, more attractive surroundings.
- Adequate collection and disposal facilities.
- Adoption and proper enforcement of State

and local legislation to penalize willful offenders.

There is no magic formula for any city; but the plan most likely to succeed is a full-time, continuous program of litter control supported by all the interested groups in the community, with the full cooperation and participation of government.

If communities throughout the country join the effort, perhaps in succeeding generations the "inherited" tendency toward the disease of litter will be markedly reduced.

Project guides for leaders on various phases of litter prevention are available from Keep America Beautiful, Inc., 99 Park Avenue, New York 16, N.Y.

Epidemiological Notes

Rabies

Although only six cases of rabies in man were reported in 1958, it is worth noting that half of them were traced to bites by animals other than dogs. One case each was traced to a bite by a skunk, a fox, and a bat. This is a slightly higher proportion of infections from wildlife sources than for the previous 5 years. The relatively lesser importance of dogs in the etiology of infection in man parallels the decline in number of rabid dogs reported and an increasing number of rabies infections reported in wild animals. About 1940, 85 percent of all cases of animal rabies reported were in dogs and about 3 percent in wild animals. Since that time, cases of rabies in dogs have declined nearly 65 percent, while in wild animals there has been almost a tenfold increase in numbers reported.

The measures for control of rabies in dogs are well established; vaccination and elimination of stray dogs. On the other hand, the complex problem of controlling infection in wild animals continues to be formidable. The apparently increasing amount of rabies in wildlife is a threat not only to the health of man but also to domestic animals. The annual economic loss in cattle and horses infected with rabies by wild animals is considerable.

The extent of the task of preventing rabies in man cannot be measured by the small number of deaths. Any calculations must include the approximately 60,000 persons who receive injections of vaccine annually because of exposure to rabid animals or to animals suspected of having rabies. Investigations have been underway to develop vaccines that will not induce serious reactions but will stimulate adequate antibody responses. The optimum use of hyperimmune serum is being studied, and the development of a gamma globulin is regarded as a possibility. Pre-exposure vaccination is being considered for certain individuals, such as veterinarians and mailmen who often have contact with biting dogs.—
DR. CARL C. DAUER, *medical adviser, National Office of Vital Statistics, Public Health Service.*

Total serum cholesterol values obtained from a sample of American Indians on five reservations are significantly lower than those from a Cleveland clinic population.

Serum Cholesterol Levels in American Indians

SIDNEY ABRAHAM and DAVID C. MILLER, M.D.

AN OPPORTUNITY to examine the level of total serum cholesterol of Indians residing on five reservations in the United States was afforded when the Public Health Service, in cooperation with the U.S. Department of Interior, conducted the Indian Health Survey from October 1955 through June 1956.

Such an examination is of epidemiological interest, since an early study reported infrequent coronary heart disease among the Navajos which prompted an examination by subsequent investigators (1, 2). They found in a small sample of hospitalized Navajos a low serum cholesterol level when compared with that of a clinic group from the Cleveland population, although the Navajo dietary fat intake apparently was not much less than that of the general diet. These findings are contrary to still inconclusive evidence that a high fat intake is reflected in a high concentration of serum cholesterol in the blood and, perhaps, in an increased tendency to develop atherosclerosis (3, 4). It was theorized from these findings that

genetic factors, rather than dietary factors, were the principal cause of the low serum cholesterol level and low coronary heart disease occurrence among the Navajos. Other investigators, in studying different groups of the Navajo population, were not impressed that the Navajo mean serum cholesterol level was particularly low. They concluded that the mean level which they observed does not support the hypothesis that the low prevalence of coronary heart disease among the Navajos is a result of low blood lipids (5).

It is of particular interest, therefore, to examine the serum cholesterol levels of the American Indians in this survey and to compare these with levels of an American white population having a high mean serum cholesterol level (2). The American Indians who were examined resided on the following reservations: Acoma, N. Mex.; Crow, Mont.; Lac Courte Oreilles, Wis.; San Carlos, Ariz.; and Yankton, S. Dak. The relationship with age was also examined and is presented as additional statistical evidence concerning the level of serum cholesterol of populations (6).

Population Studied

The Indian Health Survey was initiated at the request of the 84th Congress, 1st session. The purpose was to determine "the needs and measures necessary to bring Indian health to

Mr. Abraham is statistician, Heart Disease Control Program, Division of Special Health Services, Public Health Service. Dr. Miller, formerly associate chief, Operational Research Section, Heart Disease Control Program, is now medical officer in charge, Public Health Service Indian Hospital, Tuba City, Ariz. (Manuscript received for publication February 13, 1959.)

an acceptable level." An interview was conducted with members of every household living on each of nine selected Indian reservations; usually only the adults present were interviewed. This aspect of the survey yielded estimates of the extent of illness and the extent of medical care and health facilities available. The results of these interviews are reported elsewhere (7).

Clinical examinations were conducted in selected households. The examination consisted of medical history, physical examination, and laboratory tests. The purpose was to obtain more specific information on the extent of illness and disease among Indians than was obtained by the household interview. A random sample of members of households on five of the original nine survey reservations was taken for this purpose. Household serial numbers assigned at the time of the initial house-to-house survey were used to select examinees.

Methods

Total serum cholesterol was determined by the method of Abell and associates (8). Blood samples of adult Indians were collected and shipped to the National Heart Institute Laboratory at Framingham, Mass., for determination of serum cholesterol values. The Cleveland Clinic Foundation employed a similar method in obtaining total serum cholesterol values of

the white population group used for comparison. Both the laboratories, Framingham and Cleveland, had previously established the reproducibility of their total serum cholesterol measurements (9).

State of Health

Levels were determined for clinically healthy Indians as well as for those who were found to have diseases or conditions that influence the serum cholesterol level. To conform with the practice of other reporting investigators, however, only those Indians are included here whose state of health was uncomplicated by conditions which might affect serum cholesterol. Women whose clinical records showed that they were pregnant were excluded.

Results

Table 1 summarizes the values of total serum cholesterol of clinically healthy Indian men and women residing on five Indian reservations. For men, the mean serum cholesterol levels range from a low of 193 mg. per 100 cc. for San Carlos Indians to a high of 224 mg. per 100 cc. for Crow Indians. For all reservations, Indian women show consistently lower mean serum cholesterol levels than Indian men. Women residing on the San Carlos Indian Reservation show the lowest mean serum cholesterol value,

Table 1. Serum cholesterol levels in American Indians on five reservations, by sex

Sex and reservation	Number of persons	Serum cholesterol (mg. per 100 cc.)			Age	
		Mean	Standard deviation	Range	Mean	Standard deviation
<i>Male</i>						
Crow.....	28	223.8	41.4	106-310	35.5	9.3
Yankton.....	21	209.9	38.0	154-296	35.9	10.6
Acoma.....	25	223.0	60.3	98-336	38.7	11.0
San Carlos.....	21	193.5	28.5	143-255	36.4	13.0
Lac Courte Oreilles.....	16	212.6	49.1	125-301	38.4	9.0
<i>Female</i>						
Crow.....	26	200.2	45.3	137-345	34.8	9.3
Yankton.....	15	209.1	56.5	137-335	31.0	9.5

San Carlos.....	34	189.4	41.4	114-287	32.1	8.6
Lac Courte Oreilles.....	32	199.9	45.1	92-273	38.1	9.6

189 mg. per 100 cc. Women residing on the Yankton Reservation show the highest mean serum cholesterol value, 209 mg. per 100 cc.

Data were combined for each sex without regard to reservation because of the small numbers of serum cholesterol determinations done at each location. Pooling of data seemed justified because there were no significant differences in mean cholesterol among Indians on different reservations. [Males: $F > 1.71$ ($F_{.05} < 2.46$). Females: $F > 0.77$ ($F_{.05} < 2.44$).] Although this sample is homogeneous in regard to serum cholesterol, it is recognized that certain genetic and cultural differences exist between the different tribes. Mean cholesterol levels of Indians were compared with those obtained from the Cleveland Clinic Foundation which had been used for comparison with the level of serum cholesterol of a group of Navajos. The mean levels of the Cleveland group have been found to be in the same range as the levels for other population groups (9). Since the original clinic data were divided into two age groups (2), the American Indian serum cholesterol data were similarly divided, with the age means and standard deviations comparable for both groups.

Indian men and women show a significantly lower mean serum cholesterol than Cleveland men and women for the two age groups (table 2).

Table 3. Serum cholesterol level of selected American Indian males, by age

Age group, in years	Number of males	Serum cholesterol (mg. per 100 cc.)	
		Mean	Standard deviation
20-29-----	31	193.5	29.3
30-39-----	33	227.4	47.2
40-49-----	28	217.8	51.7
50-59-----	19	216.4	45.8

Further evidence of the level of serum cholesterol of a population involves knowledge of the relationship between age and cholesterol. Ample evidence exists that serum cholesterol levels are, in part, dependent on age. Populations with high serum cholesterol generally show a significant rise in serum cholesterol after the thirties, while populations with low serum cholesterol do not show such a rise during this period (6). On the other hand, there are significant increases in serum cholesterol with age in the younger age group to about the thirties in both low and high serum cholesterol populations.

In the low serum cholesterol populations, the mean serum cholesterol reached a plateau after the thirties in the Naples, Italy, area (6).

Table 2. Serum cholesterol levels by age of selected American Indians and a Cleveland white group

S.D.—Standard deviation.

Table 4. Statistical tests of the presence of significant age-cholesterol relationship and of departure from linearity of selected American Indian males

Age group, in years	F test	
	Linear trend	Departure from linearity
20-39-----	10.49	0.73
40-59-----	.05	1.50

¹ Significant at 1 percent level.

From the early thirties to the fifties, the level of serum cholesterol in low-income working men of Madrid, Spain (10), tended to decline instead of rising so that the cholesterol levels at these ages were much lower than those of high serum cholesterol level populations.

In high serum cholesterol populations, such as middle-income men in Minnesota (11), professional men in Madrid (10), and Jewish and Italian workers in New York (12), serum cholesterol levels show a rise into the fifties. It should be noted, however, that the study of the age-cholesterol relationship in a high serum cholesterol population in New York did not determine significant age-cholesterol relationship beyond the thirties (13).

Table 3 shows the mean serum cholesterol level of Indian men by age. The mean serum cholesterol rises from ages 20 through 39 years, levels off, and remains fairly constant in the older ages. In order to test the significance of the age-cholesterol relationship, analysis of variance and regression analysis were made.

This age-cholesterol relationship analysis was made for age groups in which *F* tests indicated no significance of deviation from linearity. For Indian men, *F* tests of linearity of age-cholesterol relationship indicated two age groups, 20-39 years and 40-59 years. *F* tests also show that for Indian men there is a significant age-cholesterol relationship in the younger age group, 20-39 years. Significant age-cholesterol relationship is not evident in the older age group, 40-59 years. Statistical tests of the presence of significant age-cholesterol relationship and of the departure from linearity are presented in table 4.

Regression equations for two age groups showing the relationship between age and cholesterol are presented in table 5. For the younger age group there is a significant increase in total cholesterol level, averaging about 3 mg. per 100 cc. per year. In the older age group the average increase is less than one-half mg. per 100 cc. per year, which is not a significant increase.

Table 5 also shows that the predicted mean serum cholesterol value determined from the regression equation for males of ages 20-39 years with an average age of 29.2 years is 211 mg. per 100 cc. The corresponding predicted mean serum cholesterol value for males of age 40-59 years, with an average of 47.3 years, is 217 mg. per 100 cc.

Significant age-cholesterol relationship displayed in the younger age group of the American Indian series is similar to the serum cholesterol level pattern of change with age found in the younger age group of both low and high serum cholesterol populations. The fact that

Table 5. Age and serum cholesterol level relationship of selected American Indian males

Age group, in years	Number	Age		Serum cholesterol (mg. per 100 cc.)				Standard error of slope
		Mean	Standard deviation	Mean	Standard deviation	a ¹	b ¹	
20-39-----	64	29.2	6.1	210.9	39.9	133.2	+2.66	² 0.82
40-59-----	47	47.3	5.5	217.1	50.0	203.4	+ .29	³ 1.33

¹ The values for *a* and *b* are constants with regression equation: cholesterol = *a* + *b* (age). The average annual change of serum cholesterol concentration in mg. per 100 cc. is indicated by the regression coefficient *b* in the regression equation. *X* is equal to age in years; *y* is equal to serum cholesterol level.

² Slope significantly different from zero slope.

³ Slope is not significantly different from zero slope.

serum cholesterol does not continue to rise after age 39 years in the Indian group places this group in the same category as other low serum cholesterol populations which have been mentioned.

Discussion

This study attempted to determine whether level of serum cholesterol of clinically healthy Indians residing on five reservations in the United States is low or high in comparison with the levels usually accepted for general U.S. populations.

It was found that the level of serum cholesterol of this American Indian series was significantly lower than that of a sample group from the Cleveland clinic. This supports the findings of an earlier study, in which it was found that the level of serum cholesterol of a sample of hospitalized Navajos was significantly

lower than that of the Cleveland clinic group (2).

Data from this American Indian series are not available regarding the first and third variables of the interrelationship of fat content of diet to serum cholesterol level to atherosclerosis (and coronary heart disease). When three variables were examined in an earlier study, it was observed that because estimated Navajo dietary fat was not much less than that of the general American level, genetic rather than dietary factors might be largely responsible for low serum cholesterol and low coronary heart disease frequency (2).

Certain suggestive data are available regarding one genetic characteristic of this American Indian series. These data pertain to the quantum of Indian blood for each reservation and were obtained from interviews conducted during the health survey. There is some reason for overstatement of Indian ancestry because

Relation between quantum of Indian blood and mean serum cholesterol.

receipt of many benefits depends on having a minimum of one-fourth Indian blood (7). Enumerators in the survey were recruited from reservations, which may have tended to minimize overstatement of quantum of Indian blood.

If the genetic factor as measured by this subjective self-reporting of ancestry is operating to lower serum cholesterol in the Indian population, the reservations with larger proportions of full-blooded Indians should tend to have lower serum cholesterol levels. The chart shows that while there is great variation in proportion of Indians with full blood among the five reservations, there is no relationship between proportion of Indians with full blood and the mean serum cholesterol levels.

Another approach to analyzing the relationship of the quantum of Indian blood and serum cholesterol level was made by dividing the men and women into two groups, those with full blood and those with less than full blood. As indicated in table 6, these two groups, both men and women, have comparable mean ages and standard deviations. This approach confirms the previous analysis by indicating that there is no significant difference in mean serum cholesterol level between the two groups for each sex. It is apparent, however, that more objective measures of genetic characteristics would be necessary before any definite conclusions could be drawn regarding the relationship of genetic factors and serum cholesterol level.

As indicated previously, Darby and associates (5) studied two groups of Navajo In-

dians. One was centered about Ganado, a missionary center. This group consumed fat-rich foods much more frequently and had a mean serum cholesterol level which was significantly higher than the other group of Navajos studied at Pinon, an area located in the interior of the Navajo reservation. It would appear, therefore, that within an ethnically similar group there are considerable internal differences in diet and serum cholesterol patterns.

It must be recognized that various subgroups of Navajos may be ethnically dissimilar. Whether such blood lipid variations are, in turn, associated with differences in morbidity and mortality from coronary heart disease (as might be expected in view of the implication of hyperlipemia in the current popular working hypothesis of causation of coronary heart disease) suggests a fruitful area for epidemiological study of the Navajos, by far the largest American tribe of Indians and possibly the most primitive. Additional impetus to further study of the Navajos stems from another study which indicates that their death rate for cardiovascular diseases is significantly lower than that of all other American Indian tribes (14).

Summary

1. Total serum cholesterol determinations were obtained from five tribes of American Indians who were examined during the Indian Health Survey.

2. No statistically significant difference in their mean serum cholesterol levels was found among the different tribes, but the samples were

too small to conclude that clinically significant differences do not exist.

3. The serum cholesterol level of this American Indian series was significantly lower than that of the Cleveland clinic group, whose mean level is similar to that found in other surveys of American non-Indian populations.

4. The finding is in agreement with the results of a study which found that Navajo Indians have a significantly lower serum cholesterol level than that of a similar American clinic population.

5. The finding, in another study, of a higher serum cholesterol level among one subgroup of the Navajos and of a significantly lower mean level among another subgroup suggests important environmental factors at work among this ethnic group. The circumstance lends itself favorably to further epidemiological study of dietary patterns, blood lipid levels, and occurrence of coronary heart disease among the Navajos.

Shellfish Sanitation Laboratory Moves

The Shellfish Sanitation Laboratory, Robert A. Taft Sanitary Engineering Center, has moved from Gulf Breeze, Fla., to Purdy, Wash. The new mailing address is: U.S. Department of Health, Education, and Welfare, Public Health Service, Shellfish Sanitation Laboratory, Star Route Box 576, Gig Harbor, Wash.

New York City's experience with compulsory hospitalization of a hard core of recalcitrant tuberculosis patients demonstrates varied benefits for the majority of these patients.

Forcible Detention of Patients With Active Tuberculosis

ROBERT GLASS, M.D.

LEGAL REGULATIONS governing forced hospitalization of recalcitrant patients with communicable pulmonary tuberculosis apply in many States of the United States (1). Only a few States attempt enforcement, however, because most lack facilities suitable for isolation of recalcitrant patients. Programs for forcible isolation of recalcitrant patients suffering from active pulmonary tuberculosis are in effect in California, particularly Los Angeles County (2,3); Seattle, Wash. (4); Milwaukee, Wis. (5); Nova Scotia, Canada (6,7); Columbus, Ohio (8); Philadelphia, Pa. (9); and in the State of Georgia (10).

Since 1903, New York City has had regulations governing and directing forced hospitalization of recalcitrant patients suffering from communicable diseases, including tuberculosis. From 1916 to 1942, the city used for this purpose a municipal hospital on an island in the East River, accessible only by ferry boat. A guard at the hospital gate sufficed to prevent illegal departures from the hospital, which could hold 60 to 100 patients at one time. After 1942, this hospital was diverted to other uses, and the detention of these patients was tried in two other municipal hospitals in succession.

Dr. Glass is a clinician with the bureau of tuberculosis of the New York City Department of Health. The program referred to in this paper is carried out with the cooperation and assistance of the New York City Department of Correction.

The physical nature of these facilities, however, and the lack of correctional personnel were inadequate to prevent escapes.

In 1955, limited facilities for the detention of recalcitrant male patients suffering from communicable pulmonary tuberculosis were provided at the hospital of the Rikers Island Penitentiary for men, where the medical and administrative arrangements appeared to offer good prospects.

This report presents the results of the enforced hospitalization of 46 male patients successively admitted to Rikers Island Hospital in New York City from July 1, 1955, through December 31, 1957.

The New York City Program

Patients are admitted to the detention service as violators of the Sanitary Code of the City of New York, section 87, regulation 16; and section 97, regulations 3, 4, 5, and 6. These paragraphs empower the commissioner of health of New York City to remove to and detain in a hospital, patients suffering from pulmonary tuberculosis in a communicable form, who present, or are likely to present, a danger to the lives and health of other persons. These patients are known to the department of health as persons who have pulmonary tuberculosis with positive sputum or cavitory lesion and who willfully neglect to take precautions against transmission of the disease. Nonattend-

ance at chest clinics, refusal to accept hospitalization, and irregular discharges from hospitals are frequent features in the records of these patients. Chronic alcoholism is also present in a comparatively high percentage of this group.

Forcible hospitalization on the detention service is undertaken only after physicians, nurses, and medical social workers, through concerted action, have exhausted by personal contact and by mail all possible means of soliciting the recalcitrant patient's voluntary cooperation (11).

As a premonitory measure, the "hold" procedure has been instituted. Patients who in the past have habitually left the hospital against advice, have not returned from permitted leave, or have disregarded hospital regulations are given the alternative of accepting voluntary hospitalization with strict adherence to hospital regulations, or removal to the detention service under the regulations of the sanitary code. Under the "hold" procedure the patient, as well as the administration of the hospital to which he is admitted, is informed that the patient is not to be given a pass without consent of the department of health or be allowed to leave the hospital against medical advice. If the patient fails to observe the provisions of the "hold," the hospital administration reports the facts to the department of health. The patient is then removed from the hospital to the detention service by due process of law. A "hold" is placed only on those patients who, if not hospitalized, would be subject to forcible hospitalization.

Management

Patients in the detention service receive combined chemotherapy and supportive drug treatment for tuberculosis and whatever medication may be indicated for nontuberculous conditions. Transfer, under "hold," to nondetention hospitals is arranged for patients whose condition, tuberculous or other, requires methods of treatment, especially surgical, or methods of examination for which the Rikers Island Hospital is not equipped.

Sputum concentrates and cultures and drug sensitivity tests are done at the bureau of laboratories of the New York City Department of Health. All other tests and X-ray examina-

tions are performed at the Rikers Island Hospital.

Treatment of the patients is directed and supervised by a consultant on the staff of the bureau of tuberculosis of the health department, who serves as a liaison officer between the department of health and the department of correction. The consultant visits the Rikers Island Hospital every week, submitting his reports and recommendations to the director of the bureau of tuberculosis.

Decisions on transfer or release of detained patients are based on these reports and recommendations.

The medical social workers at Rikers Island and the department of health assist the patients and their families during the time of hospitalization and prepare the ground for care and assistance after discharge.

Release From Detention

Release from detention service is granted to patients whose tuberculosis becomes clinically arrested, and whose treatment and medical supervision can be safely continued outside the hospital.

Also, patients are released who, after a period of observation on the detention service, seem to have acquired satisfactory understanding of their condition and of the need for their continued hospitalization and treatment. Such patients are transferred to nondetention hospitals for the continuation of their isolation. To insure a greater degree of control, a "hold" is placed on them.

Between July 1, 1955, and January 1, 1958, 46 men were admitted to the detention service. They included one readmission case. Fourteen had moderately advanced pulmonary tuberculosis and 32, far-advanced disease. None had minimal disease. Ages ranged from 21 to 72 years with an average of 44 years. The following is the age distribution:

Age group	Number of patients
21-29	10
30-39	15
40-49	8
50-59	10
60-72	3

The majority showed features of antisocial behavior: 16 were alcoholics; 1 was a drug ad-

North Carolina Regulations

Legal regulations applying to the forced hospitalization of recalcitrant patients with communicable pulmonary tuberculosis have been enforced in the State of North Carolina for a number of years. The following appears in section 1, article 19A, chapter 130 of the General Statutes in the Cumulative Supplement of 1949, which was rewritten and ratified by the North Carolina General Assembly on March 29, 1951.

"The infectious patient that willfully fails and refuses to accept treatment as determined by the local health officer shall be guilty of a misdemeanor and shall be imprisoned in the prison department of the North Carolina Sanatorium. The period of imprisonment shall be for a period of 2 years. The medical superintendent may upon signing and placing among the permanent records of the North Carolina Sanatorium a statement to the effect that such person may be discharged without danger to the health or life of others at any time during the period of commitment. At time of discharge he will give a full statement of his reasons to the health officer serving the territory from which the person came. He also has the authority to transfer the patient from the prison division to the main sanatorium or if a veteran to a Veterans Administration hospital if the patient has demonstrated his willingness to obey the rules and regulations of the sanatorium and State laws."

dict; and 6 had records of previous violation of the criminal law. Two had to be removed to psychiatric institutions. The known duration of their disease prior to confinement varied from 3 months to 10 years, with an average of 44.7 months. The duration was less than a year for 7 patients and from 13 to 24 months for 8 patients. Twenty patients had had the disease from 25 to 60 months and 11 patients longer than that.

Each of the 46 patients had had multiple hospitalizations, the maximum being 44, and multiple irregular discharges from hospitals, with a maximum of 28. The average was 7 for hospitalizations and 5 for irregular discharges from hospitals. One patient after his first and only visit to the chest clinic, where his disease

Confined patients receive combined chemotherapy, supportive hospital treatment, and surgery, as indicated.

The law has several effects on potential irregular discharges:

- Patients know that the local health officer has the power to enforce hospitalization and treatment through court procedures. Patients transferred to the Veterans Administration Hospital at Oteen, N.C., from the prison section have continued their treatment without further trouble and have not attempted to leave against medical advice.

- Patients soon acquire an insight into their condition when they begin to improve as a result of enforced treatment. They soon develop the desire to acquire an inactive diagnosis so that they can be released and returned to their homes. Consequently they adhere to hospital rules and accept treatment.

- When a patient leaves the Veterans Administration hospital irregularly, his local health officer is notified within 24 hours. If he is receiving chemotherapy, a recommendation is also made as to drugs and duration of treatment.

- Chronic alcoholism is a large factor in failure to accept hospitalization and treatment. Enforced hospitalization provides the opportunity to help the patient with this problem.—R. E. MOYER, M.D., *chief of the tuberculosis service, Veterans Administration Hospital, Oteen, N.C.*

was diagnosed by chest X-ray and sputum examination, refused further attendance at the clinic or hospitalization.

The time elapsed since the last attendance at a chest clinic or last hospitalization varied from 2 days to 2 years, with an average of 3½ months. Twenty-two patients were brought to detention as violators of a "hold." Of the remaining 24, one-third had been out of clinics or hospitals, without medical supervision, for a period of more than 6 months.

Followup

As of December 31, 1957, the patients had spent from 70 to 447 days on the detention service prior to their release or transfer, with an average of 180 days, not considering those pa-

tients who, on December 31, 1957, were still confined to detention. One patient had to be transferred to a psychiatric institution 2 days after his admission to the detention service. He had not been diagnosed as a psychiatric case at any time previously.

Of the 15 patients discharged with arrested disease from detention hospitals up to the end of 1957, 8 originally had had moderately advanced disease and 7 far advanced. Among those discharged from nondetention hospitals after medical treatment only, one had had moderately advanced disease and another far advanced; one of the patients discharged after pulmonary resection had had moderately advanced tuberculosis and three far advanced.

Ten of the group discharged from detention with arrested disease are attending chest clinics where they are receiving medication. One patient had to be rehospitalized in a nondetention hospital because of reactivation of the disease; another was hospitalized for a nontuberculous condition, and three were lost from clinic followup and are not accounted for.

On December 31, 1957, 8 patients were still confined to the detention service, 1 patient had died there from a pulmonary hemorrhage.

Twenty-two patients had been transferred to nondetention hospitals. In this group, six men achieved arrested status; two of them had medical treatment only, and four achieved arrested status after they had accepted, and received, pulmonary surgery. After regular discharge from the nondetention hospital, these patients are now attending chest clinics.

Four patients managed to escape from the hospital to which they had been transferred from the detention service in spite of the "hold" which had been placed on them. Two patients died in nondetention hospitals, one of them from a nontuberculous condition. At the end of 1957, 10 patients were still hospitalized in nondetention hospitals, 2 of them in psychiatric institutions.

The sputum of 12 patients had become negative prior to admission to detention. Seven of them had been violators of a "hold" while hospitalized in a nondetention hospital and therefore had to be brought to detention. Their last positive sputum had been reported within a month prior to their commitment to detention.

Five patients had been recalcitrant over periods of 3 to 6 months, and their last positive sputums dated that far back.

Fifteen patients were discharged from detention as arrested cases on the basis of negative sputums and gastric cultures and stationary chest films with absence of cavitation, observed over a period of at least 6 months, and also on the basis of predetention reports and findings. Six patients transferred to nondetention hospitals achieved control of their disease and regular discharges as arrested cases. Four patients had surgery and were observed over a period of at least 3 months postoperatively to have negative cultures and stationary chest films with absence of active disease. Two were medically treated patients who were observed for at least 6 months after sputum conversion and who had stationary chest films showing no cavitation and no disease activity.

By December 31, 1957, four patients were still confined to detention, with sputum converted and chest films showing improvement or approaching stabilization over a period of less than 6 months. At nondetention hospitals the corresponding group comprised three patients. The remaining 18 patients, on detention and in nondetention hospitals, were still considered as active cases, either with sputum tests proving activity or with such reports pending.

Discussion

The reaction of the patient to forced hospitalization varied in accordance with his personality. During the consultant's visits on the detention ward, every effort was made to educate the patients about their condition and its clinical and public health aspects. Their clinical records were explained to them and, as far as possible, X-ray findings and changes outlined.

Such explanations had been offered to these patients whenever possible prior to commitment to detention, but the patients were more inclined to accept these explanations after they recognized the improvement from required treatment. The patients were shown that in many instances the prolonged stay and treatment on the detention service had produced good results, even arrest of the disease. The

impossibility of the patient's signing out at will and adherence to strict hospital rules and regulations served as important adjuncts to the medical treatment.

Prior to their commitment to the detention service, when not submitting to regular treatment, these men had not given themselves an opportunity to experience a favorable development in the course of their disease. For the first time the majority of detained patients were in a position to realize the change in their condition as this was demonstrated and explained. They also learned to understand the need for the protection of the community against infection and for their own care and medical supervision. Some of the patients who formerly had been the most recalcitrant have been attending chest clinics regularly since their release from detention or nondetention hospitals with arrested disease. Others, transferred to nondetention hospitals, have remained there without attempt to leave against medical advice and have shown full cooperation with the hospital staff. However, it is only fair to state that the poorest results were in the group of chronic alcoholics. There were six alcoholics in the group of seven who were lost from further followup after their release from detention with arrested disease or as irregular discharges from nondetention hospitals to which they had been transferred from detention.

The administrations of several nondetention institutions with tuberculosis services requested the transfer to their hospitals of patients in detention who were eligible for such a transfer to demonstrate to their own potential irregular discharges that the department of health can enforce hospitalization of recalcitrant patients who are a menace to public health and who do not accept the regulations of the sanitary code. The fact remains, however, that there exists a small hard core of individuals for whom all efforts to obtain cooperation have no effect, and for this group detention remains the only means of control (12, 13).

Summary

In June 1955, the New York City Department of Health in cooperation with the Department of Correction set aside beds at the Rikers Island

Hospital for enforced hospitalization of recalcitrant male patients with active pulmonary tuberculosis who were a danger to public health.

Forcible detention is undertaken only after exhausting all means of enlisting the voluntary cooperation of the recalcitrant patient.

A total of 46 patients, including one who was readmitted, were put on the detention service from its initiation in July 1955 through December 31, 1957. Of these, 20 became arrested cases of pulmonary tuberculosis, either while confined to the detention service or after transfer to a nondetention hospital. There were four irregular discharges from nondetention hospitals. Three patients, released from detention as arrested cases, did not report to chest clinics for continuation of their medical supervision and treatment. Three patients died, one on detention, from a pulmonary hemorrhage, and two in nondetention hospitals, one of them from a nontuberculous condition. One patient suffered reactivation of tuberculosis after his release from detention as an arrested case and while attending a chest clinic. He was rehospitalized in a nondetention hospital.

By December 31, 1957, 18 patients were still hospitalized on the detention service or in nondetention hospitals. Seven of these men showed improvement, bacteriologically and by chest X-ray, quantitatively and qualitatively, which may permit expectation of control of their condition in the future under continued hospital treatment.

The patient who had to be readmitted to detention and who was subsequently transferred for a second time to a nondetention hospital is still hospitalized there. His condition is slowly improving.

The 46 recalcitrant patients treated in about 18 months represent a small proportion of the number of persons in the area with active pulmonary tuberculosis requiring hospitalization. Stimulated by results during this limited period, preparations are being made for expansion of the forcible detention program.

Children On Their Own

Nearly 400,000 children under 12 years of age have to care for themselves while their mothers work, the Children's Bureau reports. About 138,000 of these children are under 10 years of age.

A special survey conducted for the Children's Bureau by the Bureau of the Census, which covered the arrangements made by working mothers for care of their children during May 1958, also brought out the following information:

Among children under 12 years of age, 1 in 13 whose mother works must look out for himself for varying periods. In the age group 10-11 years, 1 child in 5 is without any care while the mother works.

The number of mothers in the labor force with children under 18 years of age has more than doubled since 1950. During the period studied, a total of 2,873,000 mothers were working full time. Of their 6,665,000 children, 5,073,000 were under 12 years of age. All the children of nearly 1 out of 4 of the working mothers were under 6 years old.

Most of the children for whom day care was arranged were in charge of either fathers or relatives while their mothers worked. About 1,034,000 were looked after by nonrelatives who either came into the children's homes or cared for them in their own homes. About 24,000 children under age 3 years, and 67,000 children between the ages of 3 and 5, were in group care.

Authorities in the Children's Bureau doubt that children under 3 years should be cared for in groups. Such children ordinarily need individual attention from their mothers or from a mother substitute, they say.

Progressive Patient Care

—a challenge to hospitals and health agencies—

JACK C. HALDEMAN, M.D.

THERE has been a ground swell of interest in public health circles during the last several years in reexamining the entire concept and structure of community health services.

The last two annual meetings of the National Advisory Committee on Local Health Departments of the National Health Council have addressed themselves to such subjects. The American Public Health Association is also studying current patterns of organization of local health departments in relation to the kind of health services most needed today. There has been a rebirth of interest in the research approach to current problems of public health practice—community-oriented research aimed at developing new and better methods of public health services.

Health departments are not alone in recognizing a need to reevaluate their services. Hospitals are also facing this dilemma. On the one hand the medical profession and the American public expect and demand increased and better hospital services; on the other hand much concern is being expressed regarding the ever-rising costs of hospital care. Related to these problems is the need for more trained personnel than are available.

The public has become increasingly aware of the advantages of hospitals and nursing homes for the treatment of illness. Physicians

require the hospital's resources to apply modern techniques of effective diagnosis and therapy. Each year a larger percentage of our population is over 65 years of age, and persons in this age group require twice as much hospital care as younger persons. Some illnesses and injuries, former killers, now are effectively treated, but at the expense of many days in the hospital. Further, we may expect that better methods of financing will increase hospital use by people who do not use them now because of economic barriers.

Hospital Costs

Some of the very factors which increase hospital use also increase costs per hospital day. The advances in scientific medicine increase comfort and save lives, but more people, space, and equipment are required to do the job. In 1946 each hospital admission required an average of 4 laboratory procedures; today the average is 14. Although illness occurs on a 7-day week, hospital employees are gradually achieving the 5-day workweek. The short workweek, inflation, and the need for greater skills, plus competition for scarce personnel, has forced salaries up. An increase since 1946 of general hospital personnel from 1.5 to 2.0 employees per patient, coupled with salary increases, makes higher per diem costs inevitable.

Thus, hospitals are faced with having to provide more hospital days at higher costs per day.

Some comfort can be taken from factors which tend to offset these trends. Some medical discoveries—and hopefully more in the future—eliminate the need for hospitalization for some illnesses. Others have helped shorten the

Children On Their Own

Nearly 400,000 children under 12 years of age have to care for themselves while their mothers work, the Children's Bureau reports. About 138,000 of these children are under 10 years of age.

A special survey conducted for the Children's Bureau by the Bureau of the Census, which covered the arrangements made by working mothers for care of their children during May 1958, also brought out the following information:

Among children under 12 years of age, 1 in 13 whose mother works must look out for himself for varying periods. In the age group 10-11 years, 1 child in 5 is without any care while the mother works.

The number of mothers in the labor force with children under 18 years of age has more than doubled since 1950. During the period studied, a total of 2,873,000 mothers were working full time. Of their 6,665,000 children, 5,073,000 were under 12 years of age. All the children of nearly 1 out of 4 of the working mothers were under 6 years old.

Most of the children for whom day care was arranged were in charge of either fathers or relatives while their mothers worked. About 1,034,000 were looked after by nonrelatives who either came into the children's homes or cared for them in their own homes. About 24,000 children under age 3 years, and 67,000 children between the ages of 3 and 5, were in group care.

Authorities in the Children's Bureau doubt that children under 3 years should be cared for in groups. Such children ordinarily need individual attention from their mothers or from a mother substitute, they say.

In the long-term care unit are patients requiring prolonged care.

Home care, the fifth element of progressive patient care, extends hospital services into the home to assist the physician in the care of his patients.

By concentrating patients with similar nursing needs into separate units in this manner, the staff can be selected, trained, and adjusted in number to render maximum service. Physical facilities can be planned accordingly.

There are many unanswered questions regarding progressive patient care. Much additional research is needed. For example, we can, at this time, only speculate on its possible effects on hospital costs. Also, there are other administrative devices for improving services which should be tested.

The basic concept of progressive patient care is far broader than its relationship to the general hospital. A similar trend has been developing in the mental health field. There is growing emphasis upon the provision of community facilities and services for patients with mental disorders, in contradistinction to continued enlargement of State institutions for the care of the mentally ill. Again, the objective is to look at the patient in accordance with his particular needs. Here, application of the progressive patient care concept leads to consideration of the need for a psychiatric unit in the general hospital, diagnostic and treatment facilities on an outpatient basis at the community level, including separate clinics, a halfway house involving sheltered care and group therapy, the so-called day hospital or night hospital, sheltered workshops, and home care programs.

In modern treatment of tuberculosis, too, treatment begun in a hospital can now be continued safely and effectively in the home at a relatively early stage.

Clearly, effective patient care, directed to the total needs of the patient requires better community planning than now exists in most places. Certainly public health workers should actively participate in this planning. In many places, the health officer can be the initiator of certain aspects of the program, assuming responsibility for the organization rather than the provision of services. Public

health workers are well equipped to contribute to the long-term care and home care aspects of progressive patient care. By virtue of the multidisciplinary character of the health department staff and the focus of their training, they are accustomed to working as a team. They are also accustomed to teaching the patient and the family how to do for themselves rather than doing for them.

Before this potential contribution can become reality, however, public health people must demonstrate a willingness to supply the necessary skills. They must also fully accept, as a public health responsibility, the role of assisting the physician in the care of his patient through the provision of such services as home care programs. Actually, in places where public health workers are engaged in followup of patients discharged from tuberculosis and mental hospitals, they are already involved in some facets of progressive patient care. Extension of this responsibility to other types of long-term care, especially that associated with chronic illness and other long-term disabilities, should not be too difficult a hurdle to take. And yet, some brave new thinking is required.

It is relatively easy to determine for the community as a whole the magnitude of facilities and services needed for intensive, intermediate, and self-care, since these are measured in terms of hospitalized patients. Within the hospital, there can be a daily evaluation of the number of patients requiring each kind of care. With respect to long-term care, however, the situation is more complex. Here we are concerned with a dual problem: On the one hand are the many patients in general hospitals who could be transferred to a long-term care facility; on the other hand, many disabled persons are scattered throughout the community who would benefit by such care if it were available. The health officer and his staff are in a strategic position to assess the scope of the need for this latter type of care.

The home care segment of the program presents quite a different dilemma. For other elements, the organizational framework within which the service is provided is quite clearly that of the hospital or long-term care facility. For home care, some services are supplied by the hospital and some by other community

hospital stay. Improvement in managerial efficiency is a third factor.

Since it is clear that hospital costs and needs for scarce personnel cannot be reduced by arbitrarily cutting back services, hospital people feel it essential to review hospital operations critically; to isolate areas where increases in efficiency can be instituted without sacrificing quality of care. They feel that an important method of coping with their present dilemma lies in the systematic study of such areas and in the application of the results of research to the development of:

- More effective organizational patterns for the provision of medical services to the people.
- Better community planning for hospital facilities and better coordination of facilities within a community.
- Better techniques of administration.
- Improvement in the design of the physical plant.

This at the very same time that public health workers are asking how the health department can reorient its programs to meet more adequately the major health problems of today.

Hospital and public health personnel are both dedicated to the same goals. In the past, however, they have directed their primary efforts to opposite ends of the spectrum of the need for services. The hospital administrator has concerned himself largely with service to the acutely ill patient; the public health official has devoted his efforts principally to preventing disease; and the voluntary health agency has concentrated on gaps in health services. But there is beginning to appear unmistakable evidence of the willingness of these three groups to work together in planning complete community health programs.

Increasingly in the future, I believe, official and voluntary health agencies will sit down jointly with hospital planners to assess the need for community health facilities and services.

New Patient Care Concept

From the hospital side, there is already evolving a new concept of organization of services which shows promise, the concept of progressive patient care. This development has arisen from the attempt to better administra-

tive devices for providing the health services most needed by the people.

Many hospitals are now incorporating one or more of the progressive patient care elements in their procedures. It, therefore, behooves both hospital and public health worker to examine this concept and identify their own possible roles.

The central theme of the progressive patient care concept is the organization of facilities, services, and staff around the medical and nursing needs of the patient. Its objective is that of tailoring services to the needs of the individual patient, whether in the hospital or the home. Patients are grouped according to their illness and their need for care. The staff serving each group of patients is selected and trained to provide the kind of services needed by that group.

The progressive patient care concept envisions the general hospital of the future as the focus of both outpatient and inpatient care; as much concerned with care of the long-term patient as with the treatment of the short-term patient; as readily available for assisting the physician with care of his patient in the home as for assisting him with care of the patient in the hospital.

Five elements are usually associated with the concept of progressive patient care in the general hospital: intensive care, intermediate care, self-care, long-term care, and the extension of hospital services through organized home care programs.

In the intensive care unit, critically ill patients are concentrated in one area regardless of diagnosis. These patients are under constant audiovisual observation of the nurse, with life-saving techniques and equipment immediately available, and with nursing staff selected and trained to care for this type of patient.

In the intermediate care unit are concentrated patients requiring a moderate amount of nursing care, not of an emergency nature, many of whom are ambulatory for short periods and who are beginning to participate in the planning of their own care.

The self-care unit gathers patients who are physically self-sufficient and require only diagnostic or convalescent care which can be provided in hotel-type accommodations.

National Conference

ON AIR POLLUTION

Air pollution is an undesirable and in many cases unnecessary byproduct of human activity. Its annual cost to the Nation, estimated at between \$1.5 and \$4 billion, does not include impairments to health, which cannot yet be accurately appraised, or the psychological damages associated with living and working in a befouled atmosphere.

The first National Conference on Air Pollution, was held November 18-20, 1958, in Washington, D.C., to assess the effects of air pollution and progress toward abatement. Summaries of 15 of the technical papers presented at the conference follow. These have been selected by the editors of *Public Health Reports* with the interests of our readers in mind. Many of the others have been distributed in quantity. Complete proceedings of the conference are for sale (\$1.75) by the Superintendent of Documents, U.S. Government Printing Office, Washington 25, D.C.

Effects on Health

brief Knowledge of what air pollution does to human beings is steadily progressing.

It is clear from experiences in the Meuse Valley of Belgium in 1930, in Donora, Pa., in 1948, and in London in 1948, 1952, and 1956 that under certain meteorological conditions pollutants in the air may build up to lethal concentrations. In spite of the fact that the deaths in these acute episodes are linked to air

pollution, the mechanism by which the deaths occur is far less clearly understood. The concentration of specific pollutants in these acute episodes did not approach levels considered dangerous for working conditions in industrial plants.

Exposure to certain types of air pollutants over long periods of time can cause chronic bronchitis. This clinical entity is well recognized in Great Britain. But the exact mechanism of causation is not understood.

Other inferential evidence links air pollution with illness. Death rates for arteriosclerotic and other heart conditions and cancer of the stomach, esophagus, and lungs are higher in urban than in nonurban communities. Air

Based on a paper by James P. Dixon, M.D., commissioner, Philadelphia Department of Public Health.

agencies. This is the stage of the full sequence of care in which the health department might be expected to have a major role. A wide range of services is desirable if maximum assistance is to be given the physician in the care of his patients. Physical therapy, occupational therapy, home nursing care, social services, X-ray, laboratory services, nutritional aid, and home-maker services, to name a few. The health department has an important role in giving guidance and leadership in developing resources to provide the services needed. Some of these can be supplied by the health department. Some can more appropriately be obtained from other sources. Not always will the same agency be the provider of service. The health department must be willing to fill in the void and equally willing to promote the use of and to lend its support to services already available under other auspices.

Hospital-based services are, perhaps, more apt to give continuity of care than those based elsewhere. It is easier for one organization to assist the physician in management of the patient's full regimen of treatment, even when some of the services used are provided from other sources. A home care program must be medically supervised, and adequate medical records must be maintained. Although an underpinning of financial support for the program will be needed if services to the medically indigent are to be provided, provision should be made for patients to pay for services whenever possible. The business office of a hospital can incorporate such payment in its regular system of patient billing without difficulty.

In some communities, particularly those with several hospitals, more complete coverage may be obtained through a home care program with services emanating primarily from the health department. A great deal more study and research is needed in this area to establish principles for the most effective organization of home care programs.

Nursing service may be provided equally well from the hospital, the health department, or the visiting nurse association. In weighing the ability and responsibility to provide this, or any other part of the total services needed, hospital and public health workers will have to think in terms of services the people need, the

services they want, and the methods by which they can be furnished.

Joining Forces

Misunderstandings concerning who is responsible for what may be avoided by formal documentation of the relationship of various services. Likewise, the methodology of getting patients transferred from one service to another must be carefully worked out and understood by all participating agencies. A few communities have made a good start in this direction.

It is not uncommon for a health department to use hospital outpatient facilities for its heart, tuberculosis, or prenatal clinics. On the other hand, except for obstetrics and occasionally pediatrics, many public health workers still do not instinctively think of cooperative enterprises in which the health department and hospital jointly participate. As a local health officer some years ago, I certainly did not.

During the past few years, State health departments have been drawn closer to hospital and nursing home operations and their problems through their licensing and inspectional programs. As a rule, however, and perhaps of necessity, this has been a highly centralized function of a relatively small staff in the State health agency. The rank and file of public health workers have not participated to any considerable extent.

Health leaders are engaged in a never-ending search for ways and means to provide the kind of services the people need in ways that are most acceptable to them. In these days, when the chronic diseases and other long-term disabilities are the dominant clinical burden, neither the hospital nor the health department can escape its share of responsibility for providing the services such illnesses require.

By joining forces in a well-organized program of providing services tailored to meet patient needs, progressive patient care in its broadest concept, the resources of both the health department and the hospital can be used to far greater advantage to serve the total health needs of the community. At the same time, a vast new area of interest and of service will be opened to hospital and public health workers alike.

make respiration more difficult and increase demands on the heart. It is through such mechanisms that the irritant gases in gas warfare or in intense accidental exposure cause severe symptoms or death. The movement of fluid into the airspaces often requires time to develop into a serious threat, and the full effects may be delayed hours or several days.

Since the scrubbing action of the upper airways may prevent highly soluble gases from reaching the deep lung, it is the irritant gases of moderate and low solubility that are of particular importance in producing irritation of the deep lungs. However, there is some evidence that the simultaneous presence of particles may aid in the transport of the more soluble gases into the deep lungs.

The effects of the irritant materials already discussed do not necessarily represent permanent irreparable damage. Function has been interfered with but structure has not been irreversibly altered. Accordingly, recovery might be complete after a single nonfatal exposure, and, with low levels of exposure, the irritant consequences might not even be observable. But it is not unreasonable to infer that a person who has pulmonary edema or a heart already strained to the maximum would be able to tolerate lesser interference with the respiratory system than healthy persons. These are some of the grounds for concern about the effect of moderate concentrations of irritants on persons already under a disease stress. These functional effects have been readily apparent with the intense exposures occurring in several air pollution disasters.

These functional effects are much less evident, and possibly insignificant or absent, with the level of irritants present in the majority of cities of the United States. If health impairment of this sort is contributed to by moderate levels of contaminants, their identification and measurement may be difficult because of their threshold nature and because similar symptoms are found in individuals with disease whether the air is polluted or not.

The phenomena already mentioned deal with dynamic changes in the functioning of the lungs, not structural damage. But there is some basis for concern that continued irritation may lead to definite organic damage to the

lung tissues. This has been the implication of British studies which associate high bronchitis rates with high levels of pollution. Also, work done in Dr. H. E. Stokinger's laboratory suggests that continued exposure to low levels of ozone may produce fibrotic changes in the lungs of experimental animals. Other possible but uncertain consequences of the prolonged action of irritants might include emphysema, lowering of resistance to infection, and, through interference with the lung's excretory mechanism or otherwise, increased susceptibility to lung cancer from inhaled carcinogens.

The irritants may be in the form of gas, tiny particulates, or smog particles of oxidized hydrocarbons. The larger particulates tend to be screened out in the upper respiratory system, while the smaller are more likely to penetrate the deep lungs. The suspended particulates that typically are found widely distributed are generally in the smaller sizes which readily enter the pulmonary systems. These particulates may be irritants themselves or may intensify the action of an irritant gas.

Synergism

Of concern for some time has been the possibility that the presence of particulates might synergistically potentiate the irritant action of gases. Two major possibilities are that if irritant gases are dissolved in or absorbed on particulates, they may be carried past the normal protective mechanism of the upper respiratory passage and reach more vital parts of the lung, and that a more intense local dose may result at the point of contact than would occur by normal gas absorption, due to a high local concentration of adsorbed gas around the particle.

Experimental verification of potentiation in animal studies appears to have been accomplished by the work of Dr. Charles Labelle and Dr. Mary Amdur. Goetz has suggested that this potentiation may be of general importance and has outlined some of the characteristic interrelationships of gases and particulates which would determine whether synergism would occur or not.

We are dealing with dose-related phenomena, that is, the greater the dose or insult, the more intense the response. Over past years a widely

pollution is more intense in urban areas, but we cannot say, at present, that a cause and effect relationship has been established.

Throughout the industrialized world, lung cancer is showing a striking increase as a cause of death. Cigarette smoking has been implicated as an associated factor. However, even after correcting mortality rates for lung cancer for the effects of smoking habits, the incidence of lung cancer is still significantly higher in urban than in rural areas.

Observations indicate that a number of the pollutants in the air of some communities can produce cancer in experimental animals. This information, which does not verify that air pollution is a cause of cancer, seems to demand that the relationship between the two be explored thoroughly.

In the past, public health personnel have frequently had to operate upon generalizations and to develop control measures before the specific etiology of the disease was known. Present knowledge is sufficient to warrant a fundamental concern about the effects of polluted air upon health.

The available data demand a reasonable effort to reduce the quantity of pollution in the air and vigorous research on the specific effects of air pollution on health. Expanding industrialization in the United States and in other parts of the world make such efforts and research urgent, lest gas masks become as common as shoes.

Effects of Irritants

brief

Still uncertain is the relationship to general health impairment of the moderate concentrations of irritants found in the air of our larger cities.

Ready reactivity with tissues seems to be the only factor common to the materials classified as irritants. The biochemical reactions involved in the irritant effect differ. They may be direct and essentially corrosive in nature, as is sulfuric acid. Aldehydes presumably react

with cellular proteins. Ozone is a strong oxidant. Other irritants interfere primarily with some of the intracellular enzyme systems.

In each case, there is a direct and damaging local chemical action on the cell. In most instances this action is immediate or rapid. However, changes secondary to the direct effect can require hours or months for full development.

As defined in this paper, the category of irritants includes sulfur dioxide, sulfuric acid, acid sulfates, ozone, the nitro-olefins, recently identified and shown to be strong eye and pulmonary irritants, and a number of organic free radicals, aldehydes, and higher oxidation products of hydrocarbons.

Both the nature and the extent of the biological response are modified by the relationship between the physical and chemical properties of the irritants and the structure and responsivity of the lung. When a sufficient concentration of irritants contacts the upper airways, coughing and respiratory distress shortly result. Other effects on the lining tissues of the bronchi are interference with the action of the cilia, the lung cleansing system, or change in the rate of secretion of mucus. Damage to the cilia and change in their rate of motion have been shown to result from exposure to sulfur dioxide and synthetic smog. Gases of high solubility may not penetrate beyond the conducting airways and so the effects of the kind just described are all that might be seen.

Effects on the Alveoli

However, when irritants enter the alveoli, the consequences are different. Here the primary, immediate effects appear to be on cell permeability, or what may be called the "leakage rate." Generally, the effect leads to the passage of fluid into the alveolar spaces from the bloodstream. Also, there may be a change in the caliber of the capillary blood vessels in contact with the alveoli. The fluid increases the distance through which oxygen and carbon dioxide must diffuse, impairing their exchange, and reduces the space available for gas in the lungs. In extreme instances, whole sections of the lung may be unusable because they are literally drowned in fluid.

Thus these irritant gases in the deep lungs

Based on a paper by Norton Nelson, M.D., director, New York University Institute of Industrial Medicine, New York City.

method for measuring the effect of gases on the airway resistance of guinea pigs. She found that the presence of minute droplets of common salt solution in the air greatly increases the guinea pig's sensitivity to sulfur dioxide. In salt mist the concentration of sulfur dioxide at which the animals' airway resistance increases is very near that which occurs during episodes in which sulfur dioxide is a major pollutant.

Experimental studies of the effects on man are not so conclusive. The difficulty is in measuring the pressure gradient between two points in the lungs and the flow that corresponds to that pressure.

Dr. Arthur DuBois, University of Pennsylvania, measured pressure in the human lung by sealing the subject briefly in a telephone-booth-like box, a body plethysmograph. From a simple physical equation relating pressure and volume, lung pressure can be obtained. Using this sensitive measuring device, he found that inhaling a fine dust of charcoal powder or aluminum or a mist of India ink increased resistance to airflow two or three times. These substances are not known to be irritating, and the subjects were not aware of any resistance to breathing.

Recent studies use less direct methods based on these principles. It is known that as pressure applied to make air flow out of the lungs increases, the flow diminishes until increasing the pressure no longer increases the flow. If the subject takes in as much air as possible and then blows it out as fast as he can, the maximal rate of airflow can be measured and the effect of pressure can be ignored on the assumption that wide differences in pressure do not influence the maximal flow rate. The maximal flow rate then becomes an indirect way of estimating the flow resistance, and a drop in the maximal flow rate is assumed to indicate a rise in flow resistance.

Dr. Van Sim studied the effects of sulfuric acid mists and SO_2 in human volunteers at the Chemical Defence Experimental Establishment at Porton, England. Conventional pulmonary function tests showed no consistent change but he did observe an increase in airway flow resistance.

Several studies of persons exposed to air pol-

lution have been made in California. Dr. Hmley Motley collected data on patients with severe chronic pulmonary disease while they breathed the Los Angeles air during smog episodes. He found that the lung function of some patients improved when they breathed filtered air.

Dr. Charles Schoettlin assigned by the Public Health Service to the California State Department of Public Health has been measuring vital capacity, timed vital capacity, and maximal flow rate and making clinical evaluations of men at the Veterans Administration Center in Los Angeles. His subjects with chronic disease of the lung are matched for age and smoking history with another group of men without lung disease. These two groups will be compared with respect to their reaction to air pollution and other environmental factors.

Tumor Production

brief Certain epidemiological facets of the increasing incidence of lung cancer suggest that the atmospheric environment may be causally associated with the increase. The epidemiological data indicate areas for experimental biological efforts.

While these experiments necessarily are limited to animals, much significant information can be obtained. Such experiments, by employing large numbers of animals, permit the study of sequential changes in the development of an adverse response. Frequently, it is also possible to assess carefully the factors of host resistance in overcoming these negative effects. Protective or therapeutic measures to control the effects of air pollutants can be quantitatively studied. And, within limits, practically any state of health at any age in man can be duplicated in animals. The ultimate goal of such tests is to select laboratory circumstances most nearly duplicating the human experience.

Despite the existence of many variables, past

Based on a paper by Paul Kotin, M.D., associate professor of pathology, University of Southern California School of Medicine, Los Angeles.

accepted series of guides for safe concentrations of toxic materials in industry has been developed. I need not labor the irrelevance of standards established for these special circumstances to the general pollution situation where persons are exposed for a lifetime and perhaps around the clock, whether ill or well. Eventually we may have sufficient knowledge to set up analogous standards for air pollutants; we do not have such information now.

At present we are confronted with one of the most difficult tasks ever given biologists, extrapolation from doses producing readily measurable responses to lower and threshold levels. The quantitative relationship between dose and effect is practically never a simple linear one. In fact, with most irritant materials there appears to be a "no effect" level; very low rates of dosage can be dealt with by the body's protective mechanisms without damage.

From this standpoint spiking concentrations of relatively brief, high levels may be more damaging than the same amount of materials inhaled uniformly over a long period. Our uncertainty as to the presence of threshold, and if it exists, its quantitative level, is an additional, vexing uncertainty.

Accordingly, we have grounds for suspicion that respiratory irritants may be a significant health concern. Even for the higher concentrations found in our urban areas this is still based largely on inference from the points I have made. An effort consonant in extent with these suspicions is required to clarify the problem.

Lung Function Changes

brief Toxic substances in toxic amounts have not yet been found in community air pollution. What is found are substances in amounts sufficient to cause widespread irritation of the eyes, nose, and throat. What can these substances do to the vital function of the lungs?

Based on a paper by John R. Goldsmith, M.D., head, air pollution medical studies, California State Department of Public Health, Berkeley.

In the lungs and airways water vapor and heat are added to the air so that when it reaches the alveoli, the air is saturated with water vapor and is the same temperature as the blood. The conducting airway is lined with a layer of mucus which is continually moved toward the throat by the beating of tiny whiplike cellular projections called cilia. Larger particles of irritating air pollutants are caught in this mucus, and thus the lung is partially protected. But the smallest division of the airway, the bronchiole, with a diameter of 0.016 inch, has no layer of mucus to protect the cells which form its walls.

We are not certain whether irritants in the air cause the cells lining the bronchiole to swell up, cause the glands to increase their secretion of mucus, or produce contraction of the muscle cells which are wrapped around the bronchiole. Laboratory studies suggest all three effects are possible, and any of these reactions would decrease the caliber of the bronchiole.

One method of estimating the effects of irritating air pollution is to study resistance to airflow within the lung. Resistance to airflow is inversely proportional to the fourth power of the diameter of the conducting tube. For example, a caliber decrease of one-fifth will approximately double the resistance to airflow.

The normal person can greatly increase the amount of air with which gases are exchanged in the lung; the effort needed to produce the increase is kept to a minimum by the low resistance to airflow through the bronchi or bronchioles. An increase in this resistance means that the reserves of lung capacity are available to normal persons only with increased effort. For persons ill with asthma, emphysema, or heart trouble, who have little or no reserves, this added effort may tip the scales unfavorably.

If irritating substances produce edema and thickening of the wall of the alveoli, there certainly may be interference with gas diffusion through this wall. Dr. Geoffrey Carey and his colleagues at the University of Cincinnati have worked out methods for studying this effect and have observed some impairment of the diffusion capacity associated with air pollution episodes in Cincinnati.

The effect of air pollution on lung airway resistance has been studied in several ways. Dr. Mary Amdur at Harvard developed a

method for measuring the effect of gases on the airway resistance of guinea pigs. She found that the presence of minute droplets of common salt solution in the air greatly increases the guinea pig's sensitivity to sulfur dioxide. In salt mist the concentration of sulfur dioxide at which the animals' airway resistance increases is very near that which occurs during episodes in which sulfur dioxide is a major pollutant.

Experimental studies of the effects on man are not so conclusive. The difficulty is in measuring the pressure gradient between two points in the lungs and the flow that corresponds to that pressure.

Dr. Arthur DuBois, University of Pennsylvania, measured pressure in the human lung by sealing the subject briefly in a telephone-booth-like box, a body plethysmograph. From a simple physical equation relating pressure and volume, lung pressure can be obtained. Using this sensitive measuring device, he found that inhaling a fine dust of charcoal powder or aluminum or a mist of India ink increased resistance to airflow two or three times. These substances are not known to be irritating, and the subjects were not aware of any resistance to breathing.

Recent studies use less direct methods based on these principles. It is known that as pressure applied to make air flow out of the lungs increases, the flow diminishes until increasing the pressure no longer increases the flow. If the subject takes in as much air as possible and then blows it out as fast as he can, the maximal rate of airflow can be measured and the effect of pressure can be ignored on the assumption that wide differences in pressure do not influence the maximal flow rate. The maximal flow rate then becomes an indirect way of estimating the flow resistance, and a drop in the maximal flow rate is assumed to indicate a rise in flow resistance.

Dr. Van Sim studied the effects of sulfuric acid mists and SO_2 in human volunteers at the Chemical Defence Experimental Establishment at Porton, England. Conventional pulmonary function tests showed no consistent change but he did observe an increase in airway flow resistance.

Several studies of persons exposed to air pol-

lution have been made in California. Dr. Hurley Motley collected data on patients with severe chronic pulmonary disease while they breathed the Los Angeles air during smog episodes. He found that the lung function of some patients improved when they breathed filtered air.

Dr. Charles Schoettlin assigned by the Public Health Service to the California State Department of Public Health has been measuring vital capacity, timed vital capacity, and maximal flow rate and making clinical evaluations of men at the Veterans Administration Center in Los Angeles. His subjects with chronic disease of the lung are matched for age and smoking history with another group of men without lung disease. These two groups will be compared with respect to their reaction to air pollution and other environmental factors.

brief Certain epidemiological facets of the increasing incidence of lung cancer suggest that the atmospheric environment may be causally associated with the increase. The epidemiological data indicate areas for experimental biological efforts.

While these experiments necessarily are limited to animals, much significant information can be obtained. Such experiments, by employing large numbers of animals, permit the study of sequential changes in the development of an adverse response. Frequently, it is also possible to assess carefully the factors of host resistance in overcoming these negative effects. Protective or therapeutic measures to control the effects of air pollutants can be quantitatively studied. And, within limits, practically any state of health at any age in man can be duplicated in animals. The ultimate goal of such tests is to select laboratory circumstances most nearly duplicating the human experience.

Despite the existence of many variables, past

Based on a paper by Paul Kotin, M.D., associate professor of pathology, University of Southern California School of Medicine, Los Angeles.

experience has shown a high index of meaningfulness to man of the experimental data for animals.

All available evidence in lung cancer points to a dominant etiological role for exogenous agents present in our respiratory environment. Since cancer rarely develops subsequent to the action of a single factor, atmospheric pollution must be regarded as one of the multiple factors, operating in combination, that result in lung cancer.

The isolation and identification of specific causative agents and the determination of their mode of action have been primarily laboratory undertakings. Following are the accomplishments to date.

- Carcinogenic aromatic polycyclic hydrocarbons have been demonstrated and quantitated in polluted atmosphere of urban communities. Compounds identified include 3,4-benzpyrene and 3,4-benzfluoranthene. These agents have been used to produce skin cancers and subcutaneous sarcomas in C57 Black and strain A mice by painting and injection.

- Carcinogenic properties have been demonstrated in fractions of the atmosphere that are free of aromatic polycyclic hydrocarbons. Compounds belonging to the group of oxidation reaction products of aliphatic hydrocarbons have been used to produce skin cancers when painted on C57 Black and strain A mice.

- Ozonized gasoline has been used in inhalation chambers for the production of lung tumors in strain A and C57 Black mice. These tumors, while differing structurally from human tumors, are nevertheless unequivocally new growths. Their more indolent natural history in mice may well be a reflection of host resistance factors rather than an indication of lack of carcinogenic potency in the aerosols produced.

- Carcinogenic materials have been identified in the air in a particulate state that permits their being breathed and deposited on the lining of the lung. Many of these cancer-producing agents are chemically stable and they survive sufficiently long after emission from pollutant sources to be potential biological threats.

- Atmospheric irritants of all types, for example aldehydes and organic acids, though in themselves noncarcinogenic, may play a role in

the development of cancer by interfering with the normal flow of the mucous stream on the lining cells of the lung. This continual flow of mucus normally serves to prevent the accumulation of deposited material on the respiratory epithelium. Irritants can reduce the activity of the cilia that move the stream along, so that stasis occurs and particle accumulation can follow.

- Protein materials normally present in blood and cells are capable of freeing cancer-producing chemicals from the particles on which they are carried so that biological activity can result.

All of these findings were consistently demonstrable in various species of animals studied. Ample evidence exists to suggest that the behavior observed in the laboratory is closely analogous to the situation occurring in man. It is generally accepted that cancer develops in steps and, logically, any one of the causative links in the chain can be supplied from other environmental sources.

Irritants may come from occupational surroundings, from cigarette smoking, or from the specific biological reaction to repeated viral or bacterial infections. The carcinogenic agent may similarly be derived from other environmental sources. Atmospheric pollution, however, uniquely supplies the links necessary for the experimental induction of lung cancer. Without contrary evidence this observation, coupled with the epidemiological characteristics of the disease, strongly suggests a similar action in man.

Chronic Bronchitis

 It is difficult to compare the effects of air pollution on the health of the British people with these effects in the United States. The nature and concentration of air pollutants in the two countries differ greatly. For example, in 1952 about 30 percent of the energy derived from mineral fuels in the United States came from coal; in Great Britain 95 percent of this energy was

Based on a paper by Geoffrey C. Carey, M.D., department of social and preventive medicine, Institute of Clinical Science, Queen's University, Belfast, Northern Ireland.

derived from coal, a large portion of it soft coal burned in domestic open fires.

Air pollution levels in a typical city of the United States, such as Cincinnati, are a tenth of those experienced in London smog. Differences in housing and social conditions must also influence the incidence of specific diseases. And there is no good evidence that the diagnosis of chronic bronchitis is based on the same criteria in the two countries.

In the United States there seems to be no clear pattern of urbanization and geographic distribution among States having the highest incidence of chronic bronchitis. In Great Britain the occurrence of this disease, more than any other, increases sharply as one moves from the country through the suburbs to the centers of industrial conurbations. Other factors in the occurrence appear to be cigarette smoking, population density and domestic overcrowding, low socioeconomic status, and sex.

However, it has been demonstrated that patients who suffer from chronic bronchitis, as diagnosed by British criteria, and live in an industrial city in the United States show a worsening of symptoms with increases in air pollution.

The outstanding symptoms of chronic bronchitis are coughing and the production of excessive amounts of sputum, often containing pus. The diagnosis of chronic bronchitis should not be made until other forms of lung disease have been excluded and the patient has had increased cough and sputum either in the winter months or all year round for not less than 3 years.

Chronic bronchitis is an important cause of sickness absence in British industry. In 1951, 27 million man-days were lost from this cause in an insured working population of 25 million. The impact of the disease is even greater, as illnesses of 20 million uninsured persons are not included in this figure. England has the highest reported rate of chronic bronchitis, 65 per 100,000, and the United States the lowest, 2 per 100,000.

The effects of air pollution on health have been and are being studied in several ways in Great Britain. Four major smog episodes have occurred in London since 1948. Each was followed by an increased number of deaths com-

pared with mortality experienced in the same weeks in smog-free years. Nearly 600 excess deaths occurred after the episode of November 1948, 2,500 followed the episode of December 1952, 500 the January 1956 episode, and 400 the December 1957 incident. Very young children, old people, and persons suffering from severe heart and lung disease have been shown to be those most susceptible.

A. S. Fairbairn and D. D. Reid of the London School of Hygiene have studied mortality in the general population of Great Britain between the ages of 45 and 60 years. They reported that deaths from bronchitis are significantly related to visible smog, population density, and domestic overcrowding, and that deaths from pneumonia in men were significantly related to fog and population density.

Examination of the health records of mailmen in Britain showed a significant correlation between visible fog and sickness absence and "bronchitis wastage" (mailmen dying in service or prematurely retired because of chronic bronchitis). Over a 7-year period, the sickness experiences of a 3 percent random sample of executive and clerical government workers were similar to those of mailmen 20 years younger.

Three research groups are now carrying out prospective studies. Dr. P. J. Lawther is following some 200 chronic bronchitis patients of St. Bartholomew Hospital's wards and out-patient clinics. In an interim report he stated that the patients tend to feel worse immediately before the onset of visible fog, and that their symptoms increase and decrease in much the same pattern as simultaneous measurements of smoke and sulfur dioxide.

A Medical Research Council group is collecting daily measurements of smoke, temperature, humidity, and gaseous acid from 29 sampling stations in the city of Sheffield. The measurements are the basis for simultaneous surveys of three groups: the general population of the city, 100 chronic bronchitic patients, and 700 children who entered the first grade in 1956 and will be followed in a long-term study.

In 1957 the College of General Practitioners selected 100 of its members living in areas of varying levels of air pollution to participate in a survey. The physicians are following a num-

ber of patients throughout the year by means of clinical records and objective tests of lung function. Their reports are being collected and analyzed by the Medical Research Council.

Automobile Exhausts

brief Exhausts from gasoline-propelled vehicles contribute pollutants to the air in large quantities. In a particular area, the significance of the quantities is influenced by the availability of diluting air and by meteorological factors which govern the formation of reaction products from the primary pollutants.

In Los Angeles County it has been necessary to assess these pollutants qualitatively and quantitatively. More than 5.5 million gallons of gasoline are used each day and 2,750,000 cars and trucks are registered in the county. Cooperative studies by the Los Angeles County Air Pollution Control District, the automobile manufacturers, the Bureau of Mines, and other agencies leave no doubt that automobile exhaust is a source of air pollution.

On the average, 1,000 gallons of gasoline consumed in automotive engines releases the following substances to the air:

Substance	Number of pounds
Carbon monoxide-----	3, 200
Organic vapors-----	200-400
Oxides of nitrogen-----	25-75
Aldehydes-----	18
Sulfur compounds-----	17
Organic acids-----	2
Ammonia-----	2
Solids (zinc, lead, other metallic oxides, carbon)-----	0.3

However, individual cars vary substantially in the amount of pollutants they produce, according to engine, fuel, and operating variables.

The significance of these substances does not depend entirely on weight. If the air movement is sufficient to dilute the waste products, their concentration in the air may not reach the objectionable level. Therefore, data on Los

Angeles cannot be applied to other areas without considering factors causing dilution.

In Los Angeles the relative capabilities of these substances for reaction to form new products must also be considered. For several years it has been known that some organic compounds react photochemically to produce ozone, oxidation products such as aldehydes, and various transient and stable secondary products. Recently, methods based on infrared absorption and gas chromatography have helped to determine the relative participation of various organic molecules in the reactions of smog formation.

Certain unsaturated organic compounds appear to be more important than others in producing secondary reaction products. The possibilities of selective removal or elimination of these fast reactors should not be overlooked.

An automobile also loses substantial quantities of gasoline vapors from fuel tank and carburetor vents. The losses from both sources are minimal at temperatures of 80°F. But at 95° to 100°F., temperatures which often coincide with periods of most intense smog, the carburetor evaporation losses from Los Angeles driving approximates 40 tons of gasoline vapors an hour, a rate roughly equivalent to hydrocarbon losses from the exhausts. Tank evaporation contributes additional but lesser quantities. However, the vapors may contain less unsaturated hydrocarbons than the fuel being used.

The automobile engine is a major contributor of oxides of nitrogen, essential ingredients of the smog-forming reaction. Some authorities maintain that emissions of oxides of nitrogen as well as hydrocarbons must be reduced to abate the smog successfully in Los Angeles.

The large amounts of carbon monoxide emitted from exhausts are a benefit and a potential danger. In concentrations of more than 150 ppm it is a health hazard. In any concentration, CO affords a useful index of the distribution and degree of dilution of other constituents of exhausts. This is possible because exhaust emissions are, overwhelmingly, the principal source of CO, and the gas does not appear to be consumed by reactions in the atmosphere.

Any metropolitan area with petroleum-powered vehicles as the basis of its transportation

Based on a paper by Leslie A. Chambers, Ph.D., director of research, Los Angeles County Air Pollution Control District.

tion receives the same primary exhaust pollutants per 1,000 operating vehicles as Los Angeles. In some areas the resultant concentrations may be tolerable. In Los Angeles these exhausts are basically responsible for serious community air pollution. The pollution will increase with the number of automobiles until an effective means is found to eliminate substantially some constituents of the exhaust.

Automobile Industry

brief Air pollution affects the automobile industry somewhat differently than any other.

In manufacturing and selling almost 70 million motor vehicles now operating in the United States, the industry has encountered several aspects of air pollution abatement.

The early 1- and 2-cylinder primitive automobiles trailed billowing clouds of smoke, and by eliminating this smoke the industry achieved its first success in abating air pollution. In the 1920's, undesirably high concentrations of carbon monoxide developed during peak traffic congestion in some large cities. In the 1930's this concentration was reduced as much as 50 percent in some cities solely by increasing the efficiency of fuel-burning in gasoline engines.

The high-compression engine required gasoline containing tetraethyl lead, which created the possibility of a new hazard. After laboratory research by industry and the Bureau of Mines, the top limit of lead concentration compatible with public safety was determined and promulgated.

In the past decade, certain invisible, hard-to-measure emissions under certain atmospheric conditions and intense sunlight have been found to combine with portions of the air into something that is blamed for reduced visibility, irritation of the eyes, and other effects. To the extent that these effects are due to tailpipe emissions, they are as undesirable to us as to others.

Based on a paper by Harry A. Williams, managing director, Automobile Manufacturers Association, Detroit.

The automobile industry has authorized cooperative research, spending about \$1 million a year for the past 5 years. Some devices have been developed which show promise in the laboratory stage. Any that prove practical enough to be put into production will, of course, be marketed.

To find the cause of the undesirable emissions, basic studies of combustion have been made. Some emission seems to be unavoidable. At present, motor vehicles in the hands of users are being studied to determine if maintenance procedures can reduce typical emission. The issues that may be involved, an individual car owner's free choice of how he uses or abuses his car, are social and economic as well as scientific.

We have good cause to hope that this research will help to discover the cause of these undesirable effects and what is needed to control air pollution in every area that is affected.

Steel Industry

brief Recent accomplishments illustrate what the steel industry has done and is endeavoring to do to abate air pollution.

In 1950 the situation was less than ideal. The conditions of pollution were not even defined because there were no simple, effective, inexpensive instruments which could take a truly representative sample of the ambient atmosphere or of stack gases. That year the American Iron and Steel Institute, in behalf of the industry, signed a contract with the Industrial Hygiene Foundation of America to develop such instruments.

As a result, investigators devised an automatic smoke filter which samples the atmosphere for short periods and permits the tracing of variations in smoke intensity, a hydrogen sulfide sampler, and an instrument for measuring hourly dustfall rates.

A critical examination revealed that no one existing device enabled the industry to meet all

Based on a paper by Max D. Howell, executive vice president, American Iron and Steel Institute, New York City.

the requirements for clean air. A research project at the Harvard School of Public Health developed a new type of continuous self-forming filter revolving on a horizontal plane. It combines the versatility of a scrubbing or washing device for gases with the high efficiency of a fiber filter for particulate matter. The wools, made of blast furnace slag, are reusable and 90 percent efficient. Three pilot filters have been built and tested and a fourth is being designed.

Although the institute became actively interested in the control of air pollution in 1950, individual steel firms began much earlier to seek out and correct obvious causes of air pollution. Steam boilers were converted from coal to gas, and process heating furnaces to natural gas or electricity. Locomotives, cranes, and river boats were powered by diesel rather than steam engines.

Air is the raw material used in the largest quantity by the steel industry. More than a billion tons of air, which must be returned to the atmosphere, are used to produce 100 million tons of steel. In many instances the discharged air contains coarse and fine particles which originate in the mechanical and chemical reactions of the manufacturing processes. These particles are not the result of inefficient or sloppy practices. They are inherent in the steelmaking process.

Coke ovens have been and are sources of smoke. Those built in recent years have equipment to shorten the time of charging, vacuum charging equipment, equalizer mains, and self-sealing doors to minimize emissions. But older ovens do not lend themselves to the addition of such protective equipment.

Blast furnaces emit about 150,000 cubic feet of gas per ton of iron. With protective devices added to the furnaces, their gases contain less than 10 pounds of dust per ton. Dust catching equipment now used includes gas bleeders, venturi and orifice scrubbers, and electrostatic precipitators. One company spent \$3 million equipping four blast furnaces with precipitators and \$200,000 for gas bleeders. Another spent \$700,000 equipping two furnaces for high top pressure and installing venturi-type wet washers.

The effluent from open-hearth furnaces is the

industry's biggest and most persistent source of pollution. The United States has 926 open-hearth furnaces, representing 88 percent of the industry's steelmaking capacity. About half the dust from an open-hearth furnace is less than a micron in size and mechanical cleaners do not eliminate it effectively. Precipitators, high energy scrubbers, or filters may be required.

Four installations presently operating effective open-hearth gas-cleaning use waste-heat boilers to reduce gas temperature and electrostatic precipitators to do the cleaning. The initial installation was trouble free, but the three subsequent ones required modifications. Precipitation of dust from an open-hearth furnace still appears to be more of an art than a science.

One company equipped nine open-hearth furnaces with electrostatic precipitators at a cost of \$5.5 million. Another spent more than \$7 million adding automatic fuel and combustion control equipment to 41 open-hearth furnaces.

The new basic oxygen steelmaking process requires special equipment to suppress effluent. Spark traps and wet washers followed by moisture eliminators installed in a new 1-million-ton capacity plant cost \$2.2 million. Other companies use dry electrostatic precipitators to clean gases.

The most popular type of air-cleaning device on electric furnaces is, in effect, a giant vacuum cleaner. Dust is collected in 15-foot bags in a baghouse as the air passes through them. The bags are shaken vigorously and the dust falls into a hopper where it is mixed with water to form sludge. This type of installation, which can also be used in the basic oxygen process, is highly efficient.

Many other operations of the steel industry employ devices to reduce air pollution. Some examples are electrostatic precipitators in boiler houses, water sprays on car dumpers at ore- and coal-handling facilities, cyclone cleaners and water sprays in sinter plants, scrubbers on coal pulverizers and coal washers, waste gas controls at soaking pits, and cyclone dust catchers, electrostatic precipitators, and wet washers on scarfing beds and scarfing machines.

There is much research in progress. Old problems remain and new ones will arise. The

steel industry will attempt to solve them as speedily as possible.

Chemical Industry

brief For the chemical industry, the avoidance of air pollution and the proper use of air are conditions of doing business. Chemical producers know that many of the substances they use or produce are hazardous, and that safety of employees, neighbors, and customers must be a primary consideration. This concern undoubtedly accounts for the fact that the chemical industry has one of the best safety records in the world.

Avoidance of air pollution begins in the laboratory with the development of a process and continues through plant and process design, operation, and maintenance. A survey of the engineering departments of a representative group of companies revealed that the lowest estimate of the cost of air pollution control or avoidance is from 1 to 1½ percent of all production costs, including amortization of investment in equipment, operation, and maintenance and excluding the cost of research. We can conservatively estimate that the chemical industry spends \$200-\$250 million a year for the control or avoidance of air pollution.

The development of new processes is one of the key factors in the industry's successful attack on air pollution. Ours is a highly competitive business and efforts to develop new and more efficient processes are continuous. Since the investment in pollution control equipment and the cost of its maintenance are frequently so high, chemical engineers seek to eliminate the need for such expenditures. Of course there are continuing efforts to improve control in older processes and operations which still have useful life, and it is necessary to design, install, and operate control equipment in new processes if the process itself cannot avoid generation of pollution.

I do not mean to imply, however, that the problem is not still very much with us. We feel

Based on a paper by Gen. John E. Hull, USA (Retired), president, Manufacturing Chemists' Association, Inc., Washington, D.C.

we must continue extensive work in research and education. If only because of the know-how we have gained we have an obligation to help end air pollution not directly connected with the production of chemicals. We also have an obligation to help regulatory officials and legislators draw up and administer laws and regulations that are workable and realistically in the public interest.

The industry, through the Manufacturing Chemists' Association, has conducted workshops and conferences for people in the industry and for regulatory officials. Among its published works is the "Air Pollution Abatement Manual," a definitive compendium, kept up to date by frequent supplements. Another booklet, "A Rational Approach to Air Pollution Legislation," sets out recommended principles to be used in drafting air pollution legislation. The association also makes available experts in air pollution control to help prepare legislation or regulations and cooperates actively with government and private research agencies.

Scientific investigation probably offers the best hope for sensible and effective control of air pollution. But air pollution cannot be solved without honest, accurate public understanding; here we have been less successful. Our responsibility is not only to do the best we can to avoid air pollution but also to be honest and forthright in these matters in dealing with the public. Objective reporting, based on full scientific knowledge and understandable conclusions, is the only kind that will assist in making real progress.

Florida Phosphate Industry

brief Industry needs to intensify its research in air pollution and in control efforts. It must also inform the public of its achievements to gain an understanding ally.

This has been the experience of the phosphate industry in Florida where a pattern of industry-

Based on a paper by Howard F. Roderick, vice president, Phosphate Chemicals Division, International Minerals and Chemical Corp., Chicago.

community cooperation emerged after a period marked by complaints and damage suits.

Supplying 70 percent of the Nation's output of phosphate, growing citrus fruit, and raising cattle are the principal activities in Polk County in central Florida. The phosphate rock, which contains 2 to 3 percent fluorine, is strip mined, piped in slurry to refineries where it is dried and processed, and shipped in various forms. Cyclone collectors, precipitators, and bag collectors are used to collect the dust raised during drying and handling.

Recently the production of triple superphosphate, a highly concentrated fertilizer, has increased so rapidly that the State is now responsible for 80 percent of the Nation's output.

As the population of the county grew in step with the increase in the production of phosphates, complaints about air pollution multiplied. Citrus growers and flower growers complained about fluorine damage to crops and cattle raisers about fluorosis in cattle.

In 1955 the Florida State Legislature created a joint committee on air pollution to conduct hearings. Two years later a State law created an Air Pollution Commission. By this time several damage suits had been filed against the phosphate companies.

The phosphate producers in Polk County took no joint action until 1955, although they had invested an estimated \$6 million in effluent control equipment. My firm, International Minerals and Chemical Corp., began control measures when its plants started operating, and, by July 1959, will have spent more than \$3 million on modern waste control equipment which costs \$250,000 a year to operate.

Our research laboratory also did leaf sampling and evaluation studies to determine the cause and nature of alleged crop damage. We later found that these were pioneer studies of air pollution damage to citrus crops.

However, the mineral producers in Florida failed to recognize that the public blamed the entire industry for the air pollution and ignored a single company's efforts at control. The industry also failed to keep the public informed of the work that had been done.

Both failures have now been remedied. A Florida Phosphate Producers' Committee, formed initially to represent the six participat-

ing members at the hearings of the State legislative committee, has become a permanent organization.

It has two purposes. The first is to conduct expert, impartial scientific research into the causes and effects of air pollution in Polk County. A Washington firm, retained to do this job, has set up a field laboratory and is conducting extensive studies in the county.

The second purpose is to inform the public about the industry. A local public relations agency was hired to counsel and direct public information activities for the producers. Interviews with researchers and stories about the research work, control activities, and the industry's economic importance to the community have gained greater public understanding of the difficulties of solving air pollution.

While the final outcome of these actions is yet to be judged, I think the interim results are significant. They indicate that industry will participate in a soundly directed search for the facts concerning air pollution.

Economic Aspects

brief Losses from air pollution in the United States are estimated at \$3 to \$4 billion annually. About \$300 million is spent for control each year. These figures may not be completely accurate, but they indicate the magnitude of the economic problem.

Air pollution control has grown from consideration of smoke and fly ash to encompass the total environment. Similarly, experts concerned with improving the air have developed their skills. They now have professional standing and use portions of several academic disciplines in their work. The education of such technical personnel has only begun, but it has already made possible an increasing body of research and know-how that has solved many complex control problems.

But educating industry and the general pub-

Based on a paper by William R. Bradley, M.S., assistant director of environmental health, central medical department, American Cyanamid Co., New York City.

lie to evaluate realistically their air pollution potential has not kept pace with the training of professional personnel. General application of present knowledge is lacking. It is time that the economic benefits and burdens of control for both industry and the public are understood and appreciated.

Industry has sponsored many educational programs in pollution abatement. Such voluntary efforts in self-education and the work of scientific organizations have prompted the spending of large sums for research. The majority of industries have demonstrated their cooperation in efforts to obtain cleaner air and consider that properly constituted and fairly administered control legislation will serve as a spur to the recalcitrant. But the general public has not taken comparable steps in self-education. Certainly, complaints have outstripped the development of an understanding of the economic and social benefits deriving from abatement.

For example, many people realize that burning household rubbish and wastes in open dumps causes smoke and odor and creates a breeding place for rodents and insects. But the cost of proper incineration facilities for a municipality is staggering to them and they do not always vote funds for such facilities.

Many municipalities do not realize that the cost of garbage and refuse disposal in a sanitary landfill is approximately one-third the cost of operating proper incineration equipment. In some areas a sanitary landfill can convert marginal land into parks or industrial sites that will eventually pay their own way.

The public contributes to air pollution by its use of automobiles, heating fuel, and backyard incinerators. An informed public can help to eliminate contaminants. We know the facts about abatement, but what is the best way to disseminate them? How soon the public insists on more economical disposal of these wastes depends largely on how effectively it is informed.

Savings in Industry

Industry can best be approached by making it aware of the economy that accrues when control is planned in the blueprint stage of a new

plant. Today most dollars spent on control and equipment are written off as part of the cost of doing business. But there is a trend for increasing returns from dollars spent on control. Industry's resourcefulness has made many control installations profitable through the recovery of usable byproducts.

One plant installed a steam stripper to remove volatile benzothiazole that caused a neighborhood nuisance. The steam stripper cost approximately \$85,000; the benzothiazole recovered annually is worth about \$50,000.

The baking ovens in an enamel coating metal strip operation gave off pungent solvent fumes. Installing a catalytic oxidation unit to burn these fumes saved considerable fuel, increased production 400 percent, and lowered insurance rates 95 percent. The \$30,000 investment has more than paid for itself and in addition has gained the priceless commodity of neighborhood goodwill.

Detroit-Edison, which burns about 5.5 million tons of coal a year, has created a market for fly ash. It reacts with lime to form a durable, cementlike substance and in 1957 the company sold 105,000 tons, at \$1 a ton. Dumping the fly ash would have cost the company \$78,000. Fly ash is now used in ready-mix concrete, building blocks, slag and clay bricks, roadbase choking material, filtering media, metal polish agents, and mild abrasives, and for sand blasting and land-fill reclamation. An old liability is becoming a new asset.

A mineral processing company spent \$8,000 to install equipment to collect fines lost in grinding operations. The company hoped to write off the expenditure in 2 years, but the recovered dust was of such exceptional quality it brought \$5 a ton more than the original product. The control process grosses about \$25,000 a year.

An alfalfa mill owner learned that the cattle he grazed behind his elevators preferred alfalfa fines to their usual hay and molasses. Tests revealed the fines' protein content was higher than the regular product. Dust collection is now earning its own way.

Despite what has been accomplished, by-product recovery and development is only in its infancy and large economic rewards from abatement are yet to be realized. From industry's

dollars spent on research in abatement will come the solution of many problems for industry and for the general public.

Goals

Our goals for the future might be:

- A program to expand the education of more personnel in the profession of air pollution abatement.
- A program to inform industry and the general public of the economic benefits abatement makes possible.
- Establishment of a center to collect and disseminate existing know-how concerning abatement.
- Channeling of research funds into studies of byproduct recovery and development processes and of less expensive abatement techniques.
- Establishment of liaison between government and industry that will break down restraints or fears of punitive measures and replace suspicion with cooperation.
- Creation of a team approach between the public and industry toward cooperative responsibility and effort in abatement.

These goals, while long range in scope, can be inaugurated today so that dividends of cleaner air, mutual trust and understanding through education, and a desirable economy eventually will accrue.

Levels of Responsibility

brief The constitutional basis for control of air pollution rests with the police power of the States. Under the Constitution this power of the States includes the power to protect the health, welfare, safety, and general welfare of their inhabitants. While the police power is limited by the 14th amendment, if legislation regulating air pollution is reasonably necessary for the public welfare, it will be interpreted as a valid exercise of this power.

Nor is such legislation invalid because it might put someone out of business or require a large expenditure of money. (*Northwestern*

Laundry v. Des Moines, 239 U.S. 486, 36 S. Ct. 206, 60 L. Ed. 396).

Whether it is feasible for the State to take an active part in air pollution control depends on the locality. In 1947 California adopted a statewide statute but left actual enforcement to local air pollution control districts on the county level. This type of enabling act has since been adopted by Kentucky, New Jersey, Massachusetts, Oregon, Washington, Delaware, New York, and Florida.

The purpose of such State laws is to maintain a reasonable degree of purity of the air resources consistent with public health and welfare. Air pollution is generally defined as the presence in the air of contaminants, put there by man, in quantities and of a duration to cause discomfort to a substantial number of citizens, or which are injurious to human, plant, or animal life or property. Standards for quality and quantity of pollutants and the framework for enforcement are usually included.

The California act provides for an air pollution control district in each county to be activated only if the county board of supervisors finds that local ordinances cannot handle air pollution adequately. The board of supervisors, sitting as an air pollution control board, is vested with power to make all regulations necessary to accomplish control or abatement, or both. An air pollution control officer appointed by the board is empowered to enforce the regulations as well as the State law.

These statutes are admirably suited to a one-county problem. However, California's basic act was amended to permit counties, by appropriate action, to merge or consolidate into an overall air pollution control district. In 1955 a district comprising nine counties in the San Francisco Bay area was created by special action of the California legislature.

That year California also recognized a statewide responsibility to supplement local activity in research. The State health and safety code now provides that the State department of public health shall maintain an air sanitation program which includes study of health effects of air pollution, determination of physiological effects of air pollution on plant and animal life, determination of factors responsible for air pollution, monitoring of air pollution, de-

Based on a paper by Harold W. Kennedy, county counsel for Los Angeles County, Calif.

velopment of administrative means of control of air pollution in emergencies, and assistance to local agencies in effectuating all of these activities.

Delaware and Oregon have gone beyond the enabling act at the State level. Both have a statewide air pollution control body to make rules and regulations and provide machinery for statewide enforcement. Oregon's regulations also encourage local control programs wherever feasible.

States vary in the responsibility that they have accepted for air pollution control. Some leave the matter completely to local authorities. Most States with economies substantially dependent on heavy industry have accepted responsibility for providing enabling acts, encouraging local control programs, and creating standards by which local programs may operate.

Local Programs

Recently it was estimated that 9,500 communities in the United States had air pollution problems, but only 2,050 had adopted any legislation aimed at control. Doubtless only a small minority have enacted comprehensive programs, yet local ordinances account for 80 percent of the control programs in the Nation today.

Air pollution legislation is one of two general types or a combination of them: mere punitive ordinances setting degrees of penalties for violation of laws and regulatory ordinances whose object is abatement by prevention of the discharge of pollutants into the atmosphere. Punitive ordinances were relied upon for years, but those which attack the situation at its source are now favored.

New York City, Baltimore, Richmond, Va., and East Chicago, Ind., have recently adopted comprehensive codes including permits and inspection procedures. Because air pollution is not confined by a city's boundaries, Los Angeles and Cincinnati found it necessary to make compacts with nearby communities for cooperative control measures.

An alternative solution to such a problem is to seek State legislation providing for the creation of an air pollution control district at a higher political level than the individual city

or county. The California statute provides for such districts in each county or combination of counties.

It must be recognized that any sound program of air pollution control must be tailored to the area. Size, population, industries, nature and extent of the pollution, and the funds available must be considered. Within the local programs there may also be separate levels of responsibility for rulemaking, enforcement, hearing and deciding individual cases, and an advisory function.

The primary responsibility for administration of an effective control program rests upon local authorities in most instances, but if the local authority is too small in relation to the size of the problem, it will fail unless it receives cooperation from its neighbors or assistance from some superior governmental agency.

Regional and Federal Action

If the effects of contaminants transcend the boundaries of a particular State, no solution is possible without Federal control or an interstate compact. The Constitution states, "No State shall, without the Consent of Congress . . . enter into any agreement or Compact with another State. . . ." The courts have held that this consent may be given after as well as before the agreement between States is made. (*State v. Joslin*, 116 Kan. 615, 227 Pac. 543). Since serious air contamination is seldom solved without enforcing laws, adequate control for adjoining industrial areas in separate States must contemplate some form of regional control.

Although the control of air pollution is not among the powers explicitly given to the National Government by the Constitution, neither is the protection of public health nor the prevention of pollution in streams. However, Congress has legislated to accomplish both these aims.

The commerce clause of the Constitution would be the most reasonable provision upon which to base the control aspects of a national program of air pollution control. Essential to the use of the commerce power is that the subject of the legislation or something closely related to it crosses State lines.

Also, Public Law 159 expressly affirmed "The policy of Congress to preserve and protect the primary responsibilities and rights of States and local governments in controlling air pollution, to support and aid technical research to devise and develop methods of abating such pollution, and to provide Federal technical services and financial aid to State and local governments, air pollution control agencies, and other public and private institutions in the formulation and execution of their air pollution abatement research program. . . ."

As the contamination of our atmosphere increases in intensity, it is obvious that the various levels of government must assume additional burdens to end the threat to a basic natural resource, the air we breathe.

Adequate Monitoring

brief There is no simple formula for the right amount of air monitoring in a given community at a given time. The optimum level of monitoring is the balance between the need for information on the state of the air and the cost of obtaining this information. Inadequate monitoring could permit another Donora to occur, but superfluous and ill-planned monitoring is a serious, expensive waste.

In this paper, monitoring is defined as continuous routine measurements of air quality as distinguished from a small number of samples taken for research. Pollen counts and radiological measurements are not considered.

An estimated \$1.5 million a year is now spent on monitoring in the United States. About 10,000 communities are said to have some sort of difficulty with air pollution.

The Register of Air Pollution Analyses, published by the Public Health Service, includes all known sources of monitoring, excluding that done by industry for its own protection, up to January 1, 1956. It lists 194 communities in which measurements were made. These were

located in 30 States, the District of Columbia, and Hawaii. The Register also shows that 150 urban areas measured some aspect of particulate pollution, 81 measured gaseous pollutants, and 40 had data, not always simultaneous, for both gases and particulates.

Although the passage in 1955 of Public Law 159, the Air Pollution Control Act, undoubtedly increased activity, it seems unlikely that more than 400 cities now conduct monitoring. However, continual sampling and analysis of the air of 10,000 communities may constitute, both scientifically and economically, too much monitoring.

Monitoring has four functions: to signal the existence of pollution, to identify sources, to indicate trends, and to warn of air pollution emergencies. By its nature, monitoring is somewhat inflexible in the amount of information it yields and is often less suited to the needs of a community than spot sampling and analysis. The overall complex of pollution—malodors, excessive dust, smarting eyes, and decreased visibility—is easily detected, and monitoring can only confirm what is already known: that pollution exists.

Data obtained by air analyses can yield information on the sources of pollution. However, a clever scientist should be able to find most sources of pollution in a few days of suitable weather. It is futile to perform analyses year after year to show pollution from a given source if nothing is done to control emissions.

Monitoring can yield information about the trends in the concentration of pollutants. However, consider an actual case, a small town deluged with ashes from a sawdust incinerator. The source was detected in a few months' work, and after controls were installed on the incinerator, dustfall was reduced 90 percent. Are continuing analyses necessary?

Monitoring as a warning of a disaster caused by pollution is necessary if there is a reasonable probability of disaster. But what is a "reasonable probability?" A few years of monitoring can indicate the numerical probability of a given concentration of pollutants, but are full-scale analyses justified for a warning which will be sounded once a century?

Probably the occurrence of dangerous levels once every 10 years, or good evidence of in-

Based on a paper by James P. Lodge, Ph.D., chief, Chemical Research and Development, Air Pollution Engineering Research, Robert A. Taft Sanitary Engineering Center, Public Health Service, Cincinnati.

creases in pollution toward these levels, make a warning system defensible. But perhaps only a single substance needs to be monitored.

The principal justification for monitoring, then, must be the determination of trends in air pollution in cases so complex that trends are not obvious. Any other information from monitoring operations must be regarded as a byproduct.

However, if present monitoring programs are measured against these four functions, they must be considered inadequate. Some areas are overmonitored or wrongly monitored, or both, and many communities with serious and complex problems lack facilities for even the most cursory examination.

In many situations, routine measurements of air quality over a finite period, such as a year, to establish base levels can serve very well. The levels may then be compared with subsequent spot measurements.

Consequently, we should examine the existing routine analyses, define their aims, and see if they are the best and most economical method of achieving these aims. We need to determine where monitoring is actually required. And we need research to produce the analytical methods and tools that will make monitoring less expensive and to devise control equipment that decreases emissions to the atmosphere.

A Rational Approach

brief The rational approach to control of atmospheric pollution in any specific area is based on two precepts: reasonable use of the atmosphere for the disposal of airborne waste materials and sufficient control of pollution to prevent a nuisance or a detrimental effect on health or property.

In developing criteria for the application of control equipment and techniques, the nature and scope of the pollution must be clearly understood. Air pollution is generally complex because of variations in the character of

the contaminants, the diversity and intermingling of industrial and community sources of pollution, and the influences of topography and weather on its distribution and concentration.

Difficulties also arise from variations in the effects of contaminants on man, animals, vegetation, and property. These effects may be experienced in only a small area near the source or over an entire region.

The majority of foreign substances discharged to the atmosphere by the activities of man combine in effect to produce contaminants which are classified as aerosols or gases. Aerosols are the solid and liquid particles generated by combustion, mechanical action, and chemical reaction. They reduce visibility, cause damage to property and to vegetation, injury to animals, and, to an unknown extent (at least at present), affect the health of man. Gaseous contaminants are believed to be significant in relation to effects on health and damage to property and vegetation, and as nuisances.

Sources of pollution tend to be grouped at centers of population, and thus to be concentrated within a given area, but topographic and meteorologic factors may cause the pollutants to be widely dispersed.

A cursory examination of the air pollution problem would favor establishment of universal concentration limits at the source. But such an approach is invalid both technically and economically since it would require all areas to meet the degree of control required for the most susceptible area. Furthermore, the concentration of pollutants at the source is not an acceptable measure of the effects.

However, a baseline limit above which pollution concentration is not tolerable under any conditions should be set. Two factors must be considered in setting such a limit. One, the degree of control for any single source must be such as to prevent obvious damage to property and vegetation, obvious injury to animals, and obvious detriment to health. Two, the limit established for each industry must prevent the combined sources within the area from causing serious damage to property and vegetation, serious injury to animals, and any detriment to health under the most adverse weather conditions. The maximum limits of tolerance must

Based on a paper by Andrew H. Rose, Jr., chief of engineering research and development, Air Pollution Engineering Research Program, Robert A. Taft Sanitary Engineering Center, Cincinnati.

be continually revised on the basis of new knowledge or changes in the affected area.

The engineering approach is to limit pollutants at the source so that the combined concentration from all sources in the environment will not be detrimental to health and property or cause nuisances, while allowing the atmosphere to function as an acceptor of emitted waste.

A high degree of control at the source is not always feasible within the economic capabilities of the specific area. It must be recognized that the costs of source control are borne indirectly by society but that the costs of the effects of air pollution in the environment are borne directly. Successful application of control at the source must therefore depend on the sagacity of a compromise between the cost and the desired end.

Citizen Participation

brief

In the past 6 years, Philadelphia has developed a practical program of air pollution control by involving the community in basic policy decisions. Experience has convinced us that lay participation in planning control measures is healthy, sound, and one of the best ways to explore and use community sentiment.

Philadelphia's Home Rule Charter, adopted in 1951, directed the Air Pollution Control Board, an 8-man advisory body to the health department, to prepare a comprehensive code for submission to the city council. The legislative base for public health laws rested on miscellaneous municipal ordinances, some dating back to the 19th century. The Air Pollution Control Code, adopted in 1954, grew out of this mandate to review, consolidate, and improve the city's ordinances. Specific regulations were later appended to the code.

Community participation began with the drafting of the code, which was thoroughly reviewed by industry and the lay public in the course of its adoption. Primary assistance came from the chamber of commerce and civic organizations.

Based on a paper by Donald C. Wagner, managing director, City of Philadelphia.

We found that using adequate community representation to help draft the code and regulations avoided many later difficulties. Such representation provided the administrator with a means of educating key members of the community as well as giving him a sense of what the citizen expected from the proposed legislation.

Adequate representation also led to an accommodation of conflicting points of view. Later when the proposed legislation was discussed at public hearings, members of the community as well as the administrator and the legislator defended its validity, fairness, and reasonableness.

When the regulations went into effect, the industries which had participated in the drafting were, if not enthusiastic, at least well informed about them, and the individual attitudes that industry's representatives displayed in advisory committee meetings had already been softened in group discussion. Finally, citizens' participation made available to the city the best talent in the community, talent which, ordinarily, could not be purchased.

Two examples of our methods follow. Open burning at dumps and auto wrecking yards was ended January 1, 1958, in Philadelphia. While the city was still involved in a legal battle over the ban on burning refuse, an advisory committee began writing regulations for sanitary landfill, which would replace burning as a means of disposal.

The committee included the operator of a dump, an attorney who was contesting the ban, a professor of civil engineering, a person experienced in city planning, the engineer in charge of the municipal incinerator, a member of the chamber of commerce, and two citizens who were familiar with the advantages of various methods of refuse disposal. Despite some strongly anti-theoretical points of view, the members drew up a set of regulations that were in the public interest and later were unopposed at public hearings.

In investigating rendering plants, the staff of the air pollution control section found that the general insanitary conditions as well as the plant odors necessitated a comprehensive approach.

The staff drafted regulations that they considered ideal, and a 15-member advisory com-

mittee reviewed them before appointing a subcommittee to work on them. The latter group included the owner of a rendering plant, an attorney representing the industry, an industrial physician, an official of the union that represented workers in the industry, and a veterinarian. They reviewed the draft and recommended changes and additions.

Their draft was again reviewed by the parent committee, inspected by the board of health, the top-level citizens advisory body, and the Air Pollution Control Board. This process, if somewhat prolonged, resulted in regulations that satisfied staff and industry and that were uncontested in public hearings.

Such procedures have worked in Philadelphia. For some reason, the logical processes of a group differ substantially from the thinking of the individual persons in the group. Each person is willing, or forced by the dynamics of

the situation, to abandon some personal interest in favor of a solution satisfactory to all.

We have also found that if an agency expects assistance from industry, the agency must be ready to reciprocate by acting as a consultant in air pollution control. Because of its contacts and experience, the agency is often able to point out pitfalls and indicate methods of control that have succeeded previously. The agency's function as consultant thus aids in preventing air pollution and eases its task of enforcing regulations.

As evidence of the success of these methods, in the past 6 years we have eliminated open burning on dumps, initiated a multimillion-dollar incinerator system, abolished coal-burning engines and industrial smokestack nuisances, and guided industries in installing major control facilities. The air in Philadelphia is measurably improved.

Status of Fluoridation in Community Water Supplies

By the end of 1958, 1,778 communities, supplied by 960 water systems, had adopted the procedure of adjusting the fluoride content of their drinking water. This represents a gain for the year of 4.2 percent in the population protected by controlled fluoridation.

During 1958, 145 communities with a total population of 1,449,155 adopted fluoridation. These places include Mobile, Ala., Peoria, Ill., Atlantic City, N.J., and 142 smaller cities and towns scattered throughout the United States. During the year, two communities with 15,000 persons discontinued fluoridation, the smallest number to suspend fluoridation in any year since 1951.

The communities which adopted fluoridation during 1958 include 9 cities with populations of 25,000 to 250,000, 96 communities with populations of 2,500 to 25,000, and 46 towns with populations of less than 2,500.

It is estimated that approximately 118 million people are using water from community sources. Of this number 35,240,000, or about 30 percent, are drinking water with controlled fluoride concentrations which provide optimum protection for preventing dental caries. In addition, about 7 million people obtain drinking water from community sources which naturally contain the recommended fluoride concentrations.

British Caribbean Water Supply

EDWARD W. MOORE

ALTHOUGH the geography, geology, and meteorology of the British Caribbean territories vary so much that generalizations cannot be made about the quantity and quality of their water supplies, there are some common administrative problems relating to these supplies.

The territories to which I refer consist of British Guiana and the newly created West Indian Federation, which comprises Trinidad, Jamaica, Barbados, and the Leeward and Windward Islands. The federation represents a land area of 8,000 square miles, containing a population of about $3\frac{1}{2}$ million. British Guiana has 83,000 square miles and less than a half million population.

One of the common problems of these territories is lack of sufficient money with which to develop waterworks that would approach United States standards in quantity and quality. Only the larger territories, such as Jamaica, with its bauxite, Trinidad, with its

oil and asphalt, British Guiana, with its bauxite and timber, and Barbados, with its rum and profitable tourist trade, appear to be exceptions. The smaller, primarily agricultural islands have to sacrifice both quantity and quality to a dangerous degree.

A second problem, which tends to exaggerate the effect of the first, is the nearly complete absence of a technically educated, subprofessional group to serve as operating, maintenance, and clerical staff. The load placed on the well-trained engineers at the top, as a result of the situation, is appalling, particularly in the smaller islands. It is not unusual to find one man responsible for roads, docks, waterworks, airfield construction, and erection of power stations. These responsibilities might not be too burdensome were it possible to delegate details to subordinates, but in many situations this is either impossible or inadvisable.

Standards of operation of the waterworks were observed to be low, with some notable exceptions in the larger islands where industry has created a market for and consequently a supply of subprofessional technicians. Most of their training is on the job, for almost no adequate trade schools or technical high schools exist. Maintenance of plant and equipment is particularly difficult under these circumstances. Many well-designed water systems cease to operate properly not long after completion.

The third problem relates to the very peculiar attitude toward wasting water which was encountered in all areas except one. Very few supplies (and these only partially) are metered. The proportion wasted is certainly very high, although it is not possible to get figures.

In general, the waterworks engineers seem

Mr. Moore, who is a lecturer on sanitary engineering at Harvard University, presented this paper in slightly different form before the Committee on Sanitation and Environment, Division of Medical Sciences, National Academy of Sciences-National Research Council, on October 7, 1958. His remarks are based on observations recorded when he and Prof. George T. Bryant of the Johns Hopkins University conducted a refresher course for waterworks engineers in the British Caribbean territories. The course, which ran from March 17 to June 6, 1958, was sponsored by the Pan American Sanitary Bureau, Regional Office of the World Health Organization, in cooperation with the government of Trinidad and Tobago.

apathetic about wastage. In many cases, the result is periodic failure of the water supply. In Port of Spain, Trinidad, which is a modern city in other respects, the mains in certain areas were empty a large part of every day during the time I stayed there. From time to time, rather feeble educational campaigns are attempted, but without apparent success. Newly instituted education in water conservation in the primary schools may have more effect.

An Apathetic Public

Public disinterest in water waste appears to be partly due to the special nature of the local water systems. All rural areas, and even the villages and smaller communities, are served by mains bearing public taps ("standpipes") to which all inhabitants come for water. Piped water in houses is rare outside the strictly urban regions. Control of waste at public taps is difficult if not impossible. One never takes a trip in the country without seeing a few taps leaking badly or left open. Consequently, the city user, with water piped into his place of residence or business, can see no reason for bearing the cost of metering, or the onus of conservation, when his rural brother does what he likes without reprisal.

The outstanding exception to the general rule of apathy to water waste is Antigua, the driest of the islands. At the height of an extreme drought several years ago, potable water is reputed to have sold for as much as \$1 (BWI) a gallon. Such severe conditions developed a public intolerance for water waste, and even the public taps are now metered.

Impoundment and Turbidity

Trinidad, with plenty of rainfall in its mountainous areas, has the problem of making suitable impoundments in very rugged terrain. When impounded, water in the zone of stagnation becomes foul because of the constant warm weather. Although there are no overturns due to fluctuations in temperature, a sudden heavy rainfall may roll over the water in the reservoir by driving a wedge of cool water under the bottom layer. Reservoirs are usually equipped with drainage gates at very low levels so that

the foul bottom water can be drawn off when heavy rain is expected. Wells in the central part of the island are high in iron and require deferrization, but conventional methods are adequate.

Georgetown, British Guiana, located in an extremely water-rich area, treats a unique type of water in its filtration plant. Entering the plant with a pH value in the low 5's and color ranging above 400 units, this "black" water from the Lamaha Canal is converted into a water of normal pH value, with color not greater than 15 or 20 units. This is accomplished by liberal doses of alum and sodium aluminate (about 1 ton of alum per day for 5 m.g.d., and about one-third as much aluminate), and two stages of sedimentation. It is undoubtedly the only waterworks in the world in which manatees are deliberately placed in its open secondary sedimentation tanks to keep down growth of vegetation.

Other areas encounter problems of very high turbidities. Kingston, Jamaica, treats turbidities, which may run occasionally as high as 5,000 units, in a conventional rapid sand filtration plant, with air-scour equipped filters. Alum doses run as high as $3\frac{1}{2}$ grains per gallon. It also treats similar waters in an old but handsome slow sand filter plant by means of primary settling tanks that could well serve as yacht basins.

On Other Islands

The small, dry island of Antigua is a waterworks man's nightmare and a geologist's paradise. The northern section of this 12- by 15-mile island is limestone, yielding a niggardly quantity of very hard water. The central section is marine chert, yielding water of such high salinity as to be useless. The southern section, which is volcanic and mountainous, receives most of the small, poorly distributed rainfall and is used as the main impoundment area. Turbidities are very high, and there are no adequate filtration plants. Wells and infiltration galleries are also used in this area. It is one of the few places where a comprehensive plan for developing water resources exists, but the question of financing the plan remains unanswered.

For more than 300 years, Barbados has been emptying its wastes into one set of holes in its coralline base and drawing its water from another set. No major outbreaks of waterborne disease have been recorded, and the island is rather proud of the quality of its water. However, both the rate of draft of water and the rate at which wastes are disposed of in the so-called "suck-wells" are increasing rapidly. No one knows how long such practices can safely continue. Fortunately, the health authorities are aware of the problem and are maintaining a close watch.

Each of the other islands has its own prob-

lems of water quantity and quality and engineering difficulties in bringing water to the point of use. Heads of several hundred or a thousand feet, which have to be eliminated at pressure-break tanks along the pipelines, are commonplace.

A full presentation of the many water problems of each island is impossible in this brief report, but enough has been said to indicate that the problems of quantity and quality of water in this attractive part of the world vary fully as much as they do in continental United States, except for the difficulties associated with cold weather.

The International Health Year

Plans for an International Health Year have gained momentum with a resolution adopted by the Executive Board of the World Health Organization asking the WHO Director-General to present specific projects for the Year to the World Health Assembly in May 1959. The resolution, taken in January 1959, favored emphasis on national undertakings to be coordinated on a regional and worldwide basis.

The action followed a U.S. Senate resolution, passed in August 1958, proposing talks with other nations on the designation of an international health and medical research year, "or other methods of developing intensive international cooperation in the field of health."

In December 1958, the United Nations General Assembly also passed a resolution inviting the World Health Organization to consider organizing the Year primarily on a national basis. The purposes outlined were the spread of medical knowledge, furthering of joint scientific research, exchange of experience in the use of atomic energy in medicine, organization of mass health education on a broad scale, and provision of assistance to underdeveloped countries, including equipment, medicine, special literature, and specialists.

In anticipation that the Twelfth World Health Assembly will act favorably on the proposal, Surgeon General Leroy E. Burney has appointed an ad hoc committee to consider participation of the United States in the Year and to discuss the feasibility of establishing a national committee on the International Health and Medical Research Year. This group, which met on May 6, 1959, includes representatives of both governmental and private agencies in the health and medical fields.

A special medium extends the viability of organisms in swab specimens during prolonged transport time from the patient to Alberta's central public health laboratory, which serves an area of about 200,000 square miles.

Transport Medium for Specimens in Public Health Bacteriology

R. D. STUART, M.D., D.P.H.

DELAY during the transmission of specimens from source to laboratory most noticeably affects delicate organisms which survive poorly over a period of 24 to 48 hours. Such organisms are *Neisseria gonorrhoeae*, *Haemophilus pertussis*, and *Trichomonas vaginalis*, and also *Shigella* species when specimens are obtained on rectal swabs. The pyogenic cocci common in throat inflammation and superficial infection are usually more resistant but may be significantly affected if few in number or if transport time is prolonged. Such conditions can readily arise during epidemiological investigation carried out in remote areas.

The problem has been variously tackled in the past. Two major devices have been employed. First, cooling or freezing, which slows normal bacterial metabolism, has been used to extend viability and at the same time to diminish bacterial competition. Second, transport on culture media has been employed to increase viability by encouraging multipli-

cation, but this necessitates selective agents to limit bacterial competition. Both these methods have significant disadvantages. Methods of chilling or freezing are troublesome in initial application and add considerable additional weight and cost during transport. Methods of transport in selective culture media demand a medium appropriate to each bacterial pathogen and are limited by the availability of specific selective agents which will work equally well under a variety of environmental influences and over a greatly variable time period. Such agents do not exist for most bacteria.

A transport medium must be simple in clinical use, easy in laboratory manipulation, cheap, and of wide applicability.

The transport medium to be described has all these virtues. Introduced by Stuart (1) primarily for the transport of swabs for gonococcal culture, it was applied by Moffett, Young, and Stuart (2) to the investigation of similar material from clinics mostly within 24-hour transport distance, and later by Stuart, Toshach, and Patsula (3) to the greater transport distances found in Alberta. Its value for this purpose has been confirmed by L. LeMinor, S. LeMinor, and Combes (4) from the Pasteur Institute, Paris, France; by Wilkinson (5), from the Whitechapel Clinic, London, England; by Alin (6), from the State Public Health Laboratory, Sweden; and by DeBoyn-ton (7), Los Angeles County Health Depart-

Dr. Stuart is director of the Provincial Laboratories, Alberta (Canada) Department of Health, and professor of bacteriology, University of Alberta, Edmonton. He presented this paper to the laboratory section of the 1958 combined meeting of the Canadian Public Health Association and the Western Branch of the American Public Health Association in Vancouver.

ment, Calif., but irregularities in performance have been detected by Cradock-Watson, Shooter, and Nicol (8).

Its coincidental value for the preservation of living trichomonads in similar material was emphasized by several of the above workers. Alexander (9), in Liverpool, England, emphasized its general value for gynecological specimens. The applicability of this transport medium to other bacteria was indicated first by Stuart (10), who dealt particularly with meningococci and *Shigella* species and gave some preliminary information on the satisfactory transmission of *H. pertussis* and other respiratory pathogens. Cooper (11), in Australia, produced ample evidence to indicate the value of this transport method for all respiratory and other pathogens examined, while Stokes (12) emphasized its value in the transmission of anaerobic bacteria to a central reference laboratory. Many public health laboratories across Canada now use the method routinely for all bacterial infections when specimens have to be transported over considerable distances.

Rationale of Method

The transport method is based on two main premises explained more extensively in earlier work. Briefly these are, first, that oxidation is an important cause of bacterial death during transport and, second, that elimination of all nutrients from a transport medium is the simplest way of maintaining the bacterial status quo in specimens. Thus bacteria, if kept alive by the elimination of oxygen, remain in the same relative proportions in which they existed

in the original material from the patient. The applicability of these premises to all bacteria also obviates the necessity for using different transport culture media to suit different bacteria and makes unnecessary the frequently hopeless search for suitably specific bacteriostatic agents to control unwanted bacterial multiplication during transport. Simplicity of clinical application insures that the method is highly acceptable to physicians.

The transport medium is a soft water-agar gel, hard enough to prevent agitation during transport but soft enough to avoid cracking when a swab is pushed into it. Sodium thioglycolate was selected experimentally as the best reducing agent, but is used as thioglycolic acid, chiefly because measuring is simpler than weighing. Conversion to the sodium salt is achieved by adding NaOH to the medium, the pH being stabilized by a phosphate buffer. Calcium, as calcium chloride, was found decidedly beneficial, but its presence necessitated the use of glycerophosphate as a buffer. Calcium glycerophosphate is soluble to about 2 percent, whereas calcium phosphate is almost completely insoluble. A reduction indicator is considered desirable and methylene blue was found decidedly better than resazurin. Acid production by swab sticks and swabs is of occasional detrimental significance, but is eliminated by boiling them in buffer solution before issue. Of major importance, however, is the impregnation of these swabs with charcoal, the rationale of which has been fully described (3). This charcoal impregnation neutralizes an incompletely identified inhibitor of bacterial viability, regularly present in variable

Table 1. Results of parallel smear and culture examinations for gonorrhea in females

Year	Number of specimens	Number of positives				Percent positive	
		Total positive	Culture positive, smear positive	Culture positive, smear negative	Culture negative, smear positive	By culture	By smear
1952	2,546	323	144	143	36	89	56
1953	2,945	331	130	151	50	85	54
1954	3,039	411	180	182	49	88	56
1955	3,243	492	204	238	50	90	52
1956	3,513	482	180	246	56	88	49
1957	5,042	705	204	452	49	93	36

Transport Medium

Dissolve 6 gm. Bacto agar in 1,000 ml. chlorine-free distilled water. At the same time to another 900 ml. distilled water, add 2 ml. thioglycolic acid (Difco), 12-15 ml. $\frac{N}{1}$ NaOH (to bring to approximately pH 7.2; the amount is selected according to local experience to avoid as far as possible any final pH adjustment), 100 ml. solution of sodium glycerophosphate (commercial, 20 percent w/v in water), and 20 ml. solution of CaCl_2 (1 percent w/v in water). Add this mixture to the original melted agar. Check pH and if necessary adjust to pH 7.3-7.4. Add 4 ml. methylene blue (0.1 percent in water). Mix well and dispense in $\frac{1}{4}$ -oz. screw-capped bottles, filling to capacity. Screw caps on securely, but not tightly. Sterilize in flowing steam, avoiding overcrowding, for 1 hour. Tighten caps immediately following sterilization. After cooling, the transport medium should be colorless.

NOTE: Distillate from chlorinated water occasionally contains significant amounts of free chlorine. This must be checked rigorously. We pass all distilled water through an ion-exchange resin column before use. This water is used for all the above preparation work.

Swabs

Prepare neat swabs with good quality absorbent cotton and applicator sticks. Prepared swabs are boiled in Sorensen's phosphate buffer solution ($\frac{M}{15}$) pH 7.4 (approximately 500 swabs standing in 100

ml. buffer in 1,000 ml. beaker, boiled 5 minutes). Remove, shake off excess moisture, then dip in a 1 percent suspension of finely powdered charcoal in water. We use activated charcoal (B.D.H.), but animal charcoal (Cenco), blood charcoal (B.D.H.) and Norit have been used successfully when powdered sufficiently fine. Swirl swabs around to coat thoroughly with charcoal (swabs should be quite black when wet). Shake off excess moisture, place in cotton-plugged tubes, dry in oven, and sterilize.

Instructions Sent With Outfits

Take the specimen and insert the swab or swabs into the upper third of the medium in the small bottle. Cut off the protruding portion of the swab stick with scissors and screw the lid on the bottle tightly. This usually forces the swab down slightly and centers it in the transport medium. Label the bottle and return it with the swabs enclosed to the laboratory as soon as possible. Keep specimens in refrigerator until ready for shipment.

The swabs are sterile. They have been treated with charcoal to improve the conditions for culture.

Laboratory Handling

Grasp the end of the short swab stick firmly with a long-shanked artery forceps and apply swab to culture media in the usual way. It is important that material from the swab itself is applied to the medium surface because adhering transport medium may be deposited on a culture plate and give a false impression of a satisfactory inoculum.

amount in all batches of agar so far examined. This inhibitor becomes of considerable significance because of the absence of protein nutrients in the transport medium.

A transport kit has been described by Stuart (10), and full instructions for its preparation and use are given above.

Application of Transport Method

Gonorrhea

Culture is essential in diagnosing gonorrhea only in females; thus consideration is restricted to cervical and urethral swabs from female pa-

tients. The two swabs from each patient are placed in the same transport bottle and are cultured together, generally on Peizer's medium prepared approximately as described by Trowbridge and McConkey (13) except that Difco supplement B is replaced by a locally prepared yeast extract. Colonies are identified when necessary by the oxidase reaction, and fermentation tests are carried out as a routine.

The relative inefficiency of smear examination is adequately demonstrated in table 1, but there has never been any suggestion from physicians that the combination of smear and culture failed to detect any suspected clinical case.

Table 2. Effect of transport time on culture results¹

Time, in hours	Number of positives				Percent positive by culture
	Total positive	Culture positive, smear positive	Culture positive, smear negative	Culture negative, smear positive

Indeed, recent work by Crookes and Stuart (14) shows that culture alone, aided by a selective agent to eliminate overgrowth of coliforms, can be depended on to identify practically all infections from patients under adequate clinical control.

The effect of transport time on culture results was assessed in earlier work (table 2), but the percentages have no absolute significance. The decided drop at the 48- to 72-hour period is apparently contradicted by the rise between 72 and 96 hours. The probable explanation of this peculiar finding is that a more interested and cooperative individual took most of the latter specimens. The figures, however, support the belief that culture is still very much worthwhile even after a swab has spent 4 days in transport medium, and these findings have now been considerably improved by a new culture technique (14).

Trichomoniasis

Investigation for the presence of *T. vaginalis* is carried out routinely on all specimens received for gonococcal culture and in addition on all vaginal swabs submitted for general or special investigation. After cultures have been prepared, a small amount of material from the swab is suspended in a drop of normal saline on a slide. A coverglass is applied and the preparation is viewed by reduced illumination or by dark field for active trichomonad flagellar movement. In an earlier series of 400

consecutive specimens examined in parallel by a careful staining technique and by the above method, all clinical infestations were detected by the latter. Table 3 shows the findings in our gonococcal culture section over the past 4 years.

Dysentery

The chief value of the transport medium is its applicability to rectal swabs. The value of rectal swabs in the diagnosis of dysentery has been emphasized by Cruickshank and Swyer (15), and by Yanuet, Leibovitz, and Dentsch (16), though their general usefulness has been doubted by Thomas (17) and decried by Shaughnessy, Friewer, and Snyder (18) for enteric investigations. Most workers agree that the rectal swab to be satisfactory must be kept moist and brought to the laboratory within 6 hours or so. Yet, in a dysentery outbreak in an isolated community the doctor or public health worker, coming perhaps from some considerable distance, may with luck obtain a few specimens of feces but can never hope to investigate at all adequately the incidence or epidemiology of the disease unless he can take rectal swabs. These can readily be collected from a large number of people within a short time, but they can rarely be brought or sent to the laboratory in less than 24 hours.

Experimentally, the transport medium has regularly been found effective in maintaining viability of *Shigella* and *Salmonella* species on rectal swabs for more than 48 hours and has even been found superior to parallel feces specimens up to 4 days. The results of a recent field experience are shown in table 4. Insufficient parallel specimens were received for statistical analysis, but the physicians' increasing

enthusiasm for the transport rectal swab is revealed in its increased use for convalescents and carriers in the later stages of the outbreak.

During 1956 and 1957, 4,059 specimens were examined in the central provincial laboratory specifically for dysentery organisms. Of 3,469 feces, 100, or 2.9 percent, were positive; of 522 rectal swabs in transport medium, 32, or 6.1 percent, were positive, and of rectal swabs in ordinary tubes, 68 were all negative. (*Shigella sonnei* and *Shigella flexneri* were isolated in approximately equal numbers.) Such evidence suggests that rectal swabs in the transport medium are not inferior to specimens of feces for the isolation of *Shigella* species. Although the method has never been recommended for the investigation of *Salmonella* infections, the following strains were coincidentally isolated from these rectal swabs received in the transport medium; 1 *S. paratyphi* B, 7 *S. typhimurium*, and 1 *S. tennessee*. The effect of time of transport of rectal swabs under field conditions could be assessed in 228 instances when this time was known accurately. For 105 it was one day, and for 123, two or more days. The incidence of detection of *Shigella* was exactly 11 percent in each group.

Haemophilus Infections

Cooper (11) has shown experimentally that *Haemophilus influenzae* and *H. pertussis* re-

main alive in the Stuart swab kit for 28 days, but no figures are available from any large-scale field investigation. Dr. H. Robertson and Dr. H. O. Dillenberg, from the Provincial Public Health Laboratory in Saskatchewan, have provided me with their findings in a small outbreak of whooping cough. From 29 specimens received as swabs, cough plates, or serum slants, *H. pertussis* was isolated only once, whereas from 17 specimens received as swabs in the transport medium *H. pertussis* was isolated in 10 cases. Dillenberg also mentioned that he was able to culture *H. pertussis* from such swabs after holding periods of 3 and 4 days. *Haemophilus vaginalis*, recently described by Gardner and Dukes (19), also appears to be a difficult organism to investigate. Amies and Jones (20) in this laboratory have succeeded in isolating it from 19 out of 371 cervical swabs submitted in transport medium for routine gonococcal culture.

General Throat and Superficial Infections

The value of the described transport medium for throat pathogens has been more than adequately stressed by Cooper (11). In this laboratory over the last 2 or 3 years the transport medium has been recommended on various occasions to city and health unit medical officers. These occasions have generally concerned outbreaks of particular infections, such as diphtheria and beta hemolytic streptococcal disease, particularly when a considerable holding period was inevitable between the taking of the specimens and their delivery to the laboratory. In 1957 a total of 1,020 such specimens were received, and from these 230 *Streptococcus pyogenes*, 344 *Staphylococcus pyogenes*, and 23 *Diplococcus pneumoniae* were reported as probably significant pathogens. Nine of these pneumococci were isolated in pure culture from eye swabs, one after 4 days of transport time. This finding may indicate the value of the transport medium in such specimens from which significant growths are often difficult to obtain.

Whether or not the transport medium is advantageous in ordinary throat infections is debatable. Over the 4-month period January to April 1957, 1,180 throat swabs were received, as ordinary swabs and as swabs in transport

Amies and Jones (20) in this laboratory have succeeded in isolating it from 19 out of 371 cervical swabs submitted in transport medium for routine gonococcal culture.

General Throat and Superficial Infections

The value of the described transport medium for throat pathogens has been more than adequately stressed by Cooper (11). In this laboratory over the last 2 or 3 years the transport medium has been recommended on various occasions to city and health unit medical officers. These occasions have generally concerned outbreaks of particular infections, such as diphtheria and beta hemolytic streptococcal disease, particularly when a considerable holding period was inevitable between the taking of the specimens and their delivery to the laboratory. In 1957 a total of 1,020 such specimens were received, and from these 230 *Streptococcus pyogenes*, 344 *Staphylococcus pyogenes*, and 23 *Diplococcus pneumoniae* were reported as probably significant pathogens. Nine of these pneumococci were isolated in pure culture from eye swabs, one after 4 days of transport time. This finding may indicate the value of the transport medium in such specimens from which significant growths are often difficult to obtain.

Whether or not the transport medium is advantageous in ordinary throat infections is debatable. Over the 4-month period January to April 1957, 1,180 throat swabs were received, as ordinary swabs and as swabs in transport

medium, from out-of-town areas at transport distances of 1 to 4 days; 640 swabs were received in transport medium and 540 as ordinary swabs. The area distribution of these specimens was approximately equivalent. *Streptococcus pyogenes* was isolated from 19 percent of the ordinary swabs and from 25 percent of the transport medium swabs. This difference is of doubtful significance, but it might be considered in relation to a parallel observation that the percentage of isolations of streptococci from throat swabs in transport medium remained constant regardless of whether the specimens had been in transit 1, 2, 3, or more days, whereas there appeared to be a considerable drop in the recovery of such organisms from ordinary swabs more than 2 days old.

Because of the enthusiasm of clinical workers for the transport medium, however, it became necessary to minimize these differences in order to protect the laboratory from an inordinate amount of medium making and to restrict the use of transport outfits to health officers in distant areas or under special circumstances. Since the medium and transport outfit are now commercially available, this attitude may have to be revised.

Disadvantages of the Transport Medium

A little extra care must be used by technicians in extracting the swab from the transport jelly, and a trivial delay is imposed during inoculation of culture media by the manipulation of the short swab. Of more significance is the occasional apparent multiplication of gram-negative bacilli on transport swabs even in the absence of recognized nutrients in the transport medium. This is suggested by the finding of heavy growths of coliform bacilli (mainly *Escherichia* and *Aerobacter* species) from about 5 percent of throat swabs in transport media compared with about 1 percent from ordinary swabs. If coliforms in large numbers can interfere with the isolation of hemolytic streptococci they may be even more troublesome with gonococci, especially because they are likely to be more common on swabs from the genitalia. This supposition, raised only after the recent observations on throat swabs, has been supported by a study of laboratory rec-

ords. Of 100 consecutive culture "failures" over several years, at least 50 were associated with heavy growths of coliform bacilli.

Such observations led to the search for a selective agent which would specifically inhibit coliform bacilli while allowing the growth of all desired pathogens. This agent was particularly difficult to find in connection with *Neisseria*. Search for an agent suitable for incorporation into transport media was soon abandoned. Standardization of the time of exposure is essential to the use of any bacteriostatic agent, and transport time of specimens is completely uncontrollable. In culture plates, however, aerosporin (A) (polymyxin B sulfate) has been found to have in low concentrations a regular and specific differential activity between coliforms and pathogenic *Neisseria*, inhibiting the former and leaving the latter unaffected. The beneficial effect on the culture of gonococci achieved by adding sterile aerosporin solution to a final concentration of 1 microgram (10 units) per milliliter in Peizer's medium has been described (14), but this technique cannot easily be applied to the isolation of other bacteria. Blood agar plates are generally used for this purpose. The preparation of special batches of this routine medium with aerosporin incorporated would be impracticable in most laboratories because of its irregular use, and parallel cultures on routine and aerosporin media would be expensive and tedious.

Surface impregnation of one-half of a blood agar plate with a few drops of a 25-microgram (250 units) per milliliter of aerosporin solution, prepared by appropriate dilution in water

Table 5. Application of aerosporin technique to selected throat swabs in 89 specimens¹

³ One-half same blood agar plate after surface application of 250 units/ml. of aerosporin.

⁴ Distinctly inhibited in 6 specimens.

of the sterile powder provided for intramuscular use, is a simple and effective compromise. This is done prior to inoculation, which is carried out as soon as the plate has dried. Table 5 shows the results from 89 throat swabs, known or suspected to contain coliform bacilli, cultured on such media. Each swab was spread uniformly over the culture plate, one-half of which was the aerosporin test, the other half the routine control.

This technique has not been adopted fully into routine use, chiefly because it is only occasionally necessary. The incidence of coliform bacilli is rarely high enough to cause significant trouble, but whenever necessity has arisen the technique has proved satisfactory. All common respiratory pathogens except *Haemophilus* strains can be effectively isolated by this special technique. *Haemophilus* strains, of course, can still be recovered from the untreated portion of the plate in the usual manner.

Summary

Laboratory experience over a number of years in the use of a non-nutrient transport or holding medium for bacteriological swabs has been described. The method is simple in clinical use, easy in laboratory manipulation, cheap, and of wide applicability. Its greatest value is in the transport of delicate organisms such as *Neisseria*, *Trichomonas*, and probably *Haemophilus pertussis*, and of *Shigella* species on rectal swabs when such specimens are desirable or necessary. It has a further application certainly in the transmission of eye swabs and under special circumstances in the investigation of throat and superficial infections.

The most delicate bacteria appear to survive uniformly over a 24-hour transport period and with considerable regularity up to 48 hours. Even up to 4 days transport time, swab specimens for the diagnosis of gonorrhea in females yield more positives by culture than do corresponding smears by microscopy. Sturdier bacteria survive better.

In general the absence of nutrients from the transport medium insures that the bacterial status quo of specimens is well preserved, but very occasionally coliform bacilli appear able

to multiply even in this environment. Whenever this is likely to be a nuisance it can be counteracted easily after the transport swab reaches the laboratory by the use of aerosporin (polymyxin B sulfate) in culture media, either by incorporation or by surface application.

Study of Back Supports for Premature Infants

The effect on premature infants of a diaper-roll support to the lower back has been the subject of a research study conducted jointly by the Division of Nursing Resources, Public Health Service, and Bellevue Hospital, New York City. Data were collected at Bellevue from April to November 1958.

Round-the-clock observations of the behavior of 30 premature infants receiving routine care and a like number supported by diaper rolls have indicated thus far that the use of the roll does not result in weight gain of the prematures but may contribute to the well-being of the infants by increasing sleeping time and reducing crying. Analysis of the data, now underway, may produce new knowledge on premature infant behavior for nurses, physicians, and social scientists.

The idea for the diaper roll was conceived by Eileen Hasselmeyer, R.N., M.S., nurse consultant with the division, who was chief investigator of the study. She had noticed, several years ago, that premature infants pushed, wriggled, or squirmed until they achieved a position giving support to the lower back.

Miss Hasselmeyer has been awarded a National League for Nursing fellowship for 2 years of study toward a doctorate in the nurse education department of New York University.

Radiation Control Activities in a Local Health Department

M. R. ZAVON, M.D.

C. A. WILZBACH, M.D.

WHAT can be done to control ionizing radiation in this day of increasing awareness of its hazards? More specifically, what can be done by a local health department already burdened with all the work it can handle and besieged by cries on every side for funds for additional programs?

The Cincinnati Board of Health has met this question with a series of activities aimed at reduction of exposure to radiation. The program thus far, only a bare beginning, has been conducted with a minimum in budget, personnel, and equipment, but we believe it has proved worthwhile.

Accidental Contamination Incidents

In Cincinnati in 1952 a radium capsule, used for instrument calibration, fractured in the ordinary course of operation. By the time the situation became fully understood an entire three-story building had become contaminated, and the 220-odd employees had to be examined for possible radiation exposure. With the exception of contamination of the building there were no serious effects from this accident, but it did serve to alert the health department to the need for greater awareness of the presence and potential hazard of sources of ionizing radiation.

A fire in this same building a year later raised the specter of danger to firemen fighting the fire. As a result, with the help of the Atomic Energy Commission and the cooperation of the Public Health Service, a course on radiation for firefighters was held in Cincinnati in 1953.

In 1954 a quarter curie of polonium was spilled at a local industrial plant, and the health department assisted in the cleanup operation. Occasional calls for assistance in monitoring X-ray installations were answered, but no regular program was developed.

Development of a Program

In 1955 it became evident that an organized program of radiation control was needed. A physician with previous experience in radiation protection work, who had been hired part time as director of occupational health services, commenced the radiation control program with minimum equipment.

Two steps were taken initially. One, the State health department was asked to forward copies of radionuclide authorization reports from AEC. Two, a survey was begun of shoe-fitting fluoroscopes in use in the shoe stores of the city. Each shoe fluoroscope was inspected, and a form containing some 35 items completed. The owner was advised verbally and in writing of any glaring defects, and at the conclusion of the survey the findings were presented to the Cincinnati Board of Health. The survey, conducted by one man who had other responsibilities as well, took approximately 1½ years. In all, 34 machines were surveyed.

Dr. Zavon is director of occupational health services, Cincinnati Health Department, and assistant professor of industrial medicine at the Kettering Laboratory of the University of Cincinnati. Dr. Wilzbach is health commissioner of Cincinnati.

"Radiological Health Practice" (24 pages, self-cover, 65¢ per copy) has been prepared and published by the Program Area Committee on Radiological Health, American Public Health Association. Complimentary copies are being distributed to State health officers and State sanitary engineers.

From the experience in this survey we concluded that the cost of inspecting these machines routinely would be prohibitive. In addition, putting what amounted to a health department seal of approval on shoe-fitting fluoroscopes seemed a dubious practice in the face of the unnecessary radiation exposure that they represent. At two meetings with the shoe dealers we discussed the situation. Shortly thereafter the shoe dealers requested the board of health to ban the use of these machines. The board did so by passing a regulation leaving the standing of a city ordinance or a State law.

At this point we decided that the radiation program would benefit from outside assistance and support. Consequently, the board of health appointed a Radiation Advisory Committee, consisting of technically qualified persons from industry, labor, medicine, dentistry, and public health. The health commissioner, the director of occupational health services, and the chief of the bureau of air pollution control are ex officio members. From the committee has come advice as to procedure and priorities.

About the same time that the advisory committee was formed another major step in the control program was initiated. Working with and through the Cincinnati Dental Society, the city undertook to alert the local dental profession to the need to reduce radiation exposure for themselves and their patients to the minimum consistent with diagnostic needs. A talk to the dental society was followed by a short article in its journal. This in turn was followed by an offer to arrange for proper coning and filtration for all dental X-ray machines. Approximately 50 percent of the membership of the dental society accepted the offer.

Arrangements were made with the two largest local dental suppliers to install aluminum filters on any dental machine for a fixed maximum fee or to furnish the necessary filters to

the dentist for him to install. The added filtration was to bring the total to the 1.5 mm. recommended in the National Bureau of Standards Handbook 60 (1955).

At this writing the installation of filters is nearing completion. When it is finished, the city will arrange through the dental society for a film badge service for those dentists who wish it. Use of a film badge for 13 weeks should enable us to gain some idea of the radiation exposure of the dentist and his assistants. If indicated, office surveys and corrective action can then be undertaken.

We are now facing the question of requiring registration of all radiation sources in order to determine their location. Already working closely with the fire department, the health agency has organized a list of known radionuclide users and has advised on procedures for handling fires where radiation may be a factor. The fire department in turn has held short courses for its personnel. Other city departments and other members of the board of health are cooperating in the further development of a radiation control program. The program will be integrated into our regular operating programs insofar as possible, and regular personnel will be trained to do a continuing job.

Additional activities will be necessary in the development of a well-rounded program, but there are limitations imposed by political boundaries which can be overcome only if State authorities take action. The bureau of air pollution control in the Cincinnati Department of Public Safety has long conducted routine air monitoring for radiation, but the confines of a city are too narrow for effective control of radiation in air or water. Nevertheless, we believe that municipal departments with responsibility for air and water must be as aware of radiation sources as they would be of any other contaminant.

Cincinnati's program in radiation control, by using existing facilities and cooperating agencies wherever possible, has developed and grown without significant additional expenditures. We believe that much can be done by cities of our size, 500,000, and smaller ones, to limit or reduce exposure to radiation with available facilities and staff.

*By Arthur S. Flemming, Secretary of Health,
Education, and Welfare, at press conference on
March 16, 1959*

Public Exposure to Radiation

DURING the past 2 weeks there has been, as you know, considerable public discussion about radioactivity and the effect upon health caused by the presence of radioactive elements in wheat, milk, water, and other foods.

Some of the discussion has resulted from the release by the Public Health Service of its reports on radioactivity in milk.

I think it is desirable to emphasize several points:

1. Radiation is not new in our environment, but the problems of radiation in the nuclear age are obviously growing and will be with us from now on. These problems cannot—and should not—be minimized.

2. There are many sources and kinds of radiation, such as cosmic rays and medical X-rays, some of which contribute more than fall-out to the total radiation to which the population is exposed.

3. Many scientists are seriously concerned with the cumulative effects on human beings of repeated small exposures of radiation, and research is being done by the Public Health Service, the Atomic Energy Commission, and others to ascertain these effects. We are developing plans to enable the Food and Drug Administration to engage in research in this area.

4. Our scientific information at this time is not sufficient to evaluate precisely the long-term health effects of the small amounts of radioactivity now contained in water, air, milk, and other foodstuffs. Continuing and expanding efforts will be made to put ourselves in a position to make precise evaluations.

5. The Public Health Service has repeatedly emphasized that the amount of radioactivity

found in milk is well within the tolerable limits as established by the National Committee on Radiation Protection and Measurement. These limits are the only benchmarks now available.

6. Some of the figures in the milk studies have been misunderstood and need further explanation.

7. The Public Health Service has proposed a further major step-up in its expanding radiological health activities.

Both the Public Health Service and the Food and Drug Administration of this Department have responsibilities in this area. It is apparent that the activities carried on in connection with these responsibilities will need to be substantially strengthened in order to deal with the health problems which radiation increasingly presents.

With respect to the hazards of radiation, we should remember that according to present theory any radiation may be hazardous to health. The degree of hazard may be great or negligible depending on many factors—strength, duration of the exposure, the part of the body exposed, previous exposure, and so on.

Surgeon General Burney advises me that some of the harmful effects that can result from radiation, and about which there is concern, are genetic mutations, the shortening of the lifespan, and increased incidence of certain types of cancer, including leukemia.

The Atomic Energy Commission has been conducting studies on a broad basis for 5 years, including studies of radioactive elements in water, air, and soil as well as human bone and some foodstuffs. Studies which have been un-

dertaken more recently by the Public Health Service supplement some of the studies by the Atomic Energy Commission.

With respect to the Public Health Service's milk sampling study and the reports on it, we need to take into account a number of factors.

Milk was chosen for our initial study among the foods for several reasons. One of the radioactive isotopes of most concern is strontium-90, because this element has a much longer life than most isotopes, because in the biochemical processes of the body some strontium-90 is deposited in the bones, and because strontium-90 is present in milk. Since milk and milk products properly represent such a large part of our national diet, it is likely that a sizable proportion of the strontium-90 that stays in the body comes from milk and its products.

In addition, of course, milk is produced in all parts of the country all year and is thus readily available for uniform scientific study.

As published reports of the Atomic Energy Commission, Public Health Service, and other studies show, strontium-90 and other radioactive elements are also present in wheat, soybeans, water, air, grass, and in the soil itself.

With respect to possible misunderstandings about the figures contained in the Public Health Service monthly reports on radioactivity in milk, it is important to remember that they should be considered in relation to other figures. The National Committee on Radiation Protection and Measurement, on the basis of the scientific opinion available to it, has set maximum permissible limits for lifetime exposure of the individual to specific radiation and radioactive materials.

These limits were adapted from safety standards for persons working in close proximity to sources of radiation, such as medical X-ray technicians. The occupational permissible limits were divided by 10 to provide permissible limits for the general population.

For strontium-90, for instance, the committee's current recommendation for a maximum permissible concentration is 80 micromicrocuries per liter of water or milk. This means that on the basis of present knowledge the average concentration of strontium-90 among all items of the diet—water, meats, vegetables, bread, and so on—could be 80 micromicrocuries per

liter (or per kilogram—2.2 pounds) for a lifetime without exceeding the current maximum permissible concentration.

(A curie is the amount of radioactivity in 1 gram of radium. A micromicrocurie is one millionth of a millionth of a curie.)

Average yearly levels of radioactivity in milk are far more significant than monthly levels because the yearly averages are more accurately comparable with lifetime permissible limits. For strontium-90, for example, there was an increase in St. Louis, Mo., from 12.2 micromicrocuries in October 1958 to 20.1 in November 1958 (which then dropped back to 15.6 in December). The average level for the year ended October 1958 was 11.4 compared with 12.5 as the average level of the year ended November 1958. This yearly average is to be compared with the 80 micromicrocuries per liter currently used as the lifetime permissible concentration.

I am advised—and it should be emphasized—that these so-called permissible limits are only calculated estimates. They will be subject to change as more and better scientific data are developed about radioactive elements and their effect on the human body.

For example, there has already been some public discussion related to lowering the recommended levels for some elements, such as strontium-90. Further consideration should be given to the amount of strontium-90 which is distributed and retained in the body. A great deal more research is needed to provide data for a more accurate correlation between the amounts found in foodstuffs and their lodgment in the body.

For the time being the current maximum permissible limits represent the most informed scientific opinion available to us.

However, when the total amount of radiation to which people are exposed is increased, measures should be taken to reduce radiation over which we have some control. This led the Public Health Service to advocate several years ago the abolition of X-ray machines used in some stores for fitting shoes, and a year ago the substitution of skin tests for mass X-ray surveys as the first step in detecting tuberculosis.

Last September I discussed at a press con-

ference the range of activities conducted by the Department in the field of radiation.

We are now working with the Food and Drug Administration to determine what can be done to enlarge its capabilities for carrying out its statutory responsibilities as they relate to the field of radiation.

With respect to the Public Health Service program, the Department's budget for 1960 calls for slightly more than a doubling of the capabilities of the Public Health Service in the field of radiation. The request is for an appropriation of \$1,439,100, an increase of \$805,000 and the largest single increase in the Public Health Service. This is in addition to about \$2 million being devoted to the study of radiation by the National Institutes of Health through grants-in-aid and in its own laboratories. The expanded Public Health Service effort would be made in three categories—research, technical assistance to States and communities, and training of personnel.

Dr. Burney advises me that this research will have as its aim the development of better knowledge concerning the effects of radiation on the human body. To obtain more knowledge in this aspect of the problem, studies will be made in two types of population groups—individuals exposed to radiation in industry and individuals exposed in the course of medical diagnosis and therapy.

In addition, the research would seek to simplify and standardize tests used to measure those radiation levels which affect people. With such standardized methods, a national

system could be devised, with the help of State and Territorial public health agencies, for analyzing and exchanging information on radiation.

Technical assistance to the States and communities would include the assignment of trained Public Health Service personnel to selected State, local, and regional offices. It would also include a survey to identify and assess nationwide radiological health resources. One aspect of this survey would be to identify personnel who might be most readily trained for work in radiological health.

The training activity would cover expansion of the existing number of professionally trained persons responsible for direction of national and State program activities in radiological health. The experience gained in these training activities would be applied to the training programs conducted by State and local health agencies. I feel that these steps are essential in the fiscal year 1960, and that if taken they can provide fruitful results on which to build additional knowledge and measures for health protection against radiation.

It is quite clear that the problem of radiation in our environment is one we must learn to live with. In fact, it has always been with us. It has national and international implications of a most complex nature. As I have indicated, we need, as a first objective, to learn much more than we know now about the whole subject. Our objective in this Department is to aid in this effort in every way possible.

Human Genetics Research Training

A 5-year program to train research scientists in human genetics will begin September 1959 at the University of Pittsburgh Graduate School of Public Health. The university has received a \$16,000 grant from the Public Health Service for the first year.

Designed for students of biology with a master's degree, the course covers the hereditary aspects of various diseases, particularly those important to public health. The plan of study will be tailored to the background and research interest of the individual student. Dr. Ching Chun Li, associate professor of biostatistics and president-elect of the Society of Human Genetics, will direct the training.

dertaken more recently by the Public Health Service supplement some of the studies by the Atomic Energy Commission.

With respect to the Public Health Service's milk sampling study and the reports on it, we need to take into account a number of factors.

Milk was chosen for our initial study among the foods for several reasons. One of the radioactive isotopes of most concern is strontium-90, because this element has a much longer life than most isotopes, because in the biochemical processes of the body some strontium-90 is deposited in the bones, and because strontium-90 is present in milk. Since milk and milk products properly represent such a large part of our national diet, it is likely that a sizable proportion of the strontium-90 that stays in the body comes from milk and its products.

In addition, of course, milk is produced in all parts of the country all year and is thus readily available for uniform scientific study.

As published reports of the Atomic Energy Commission, Public Health Service, and other studies show, strontium-90 and other radioactive elements are also present in wheat, soybeans, water, air, grass, and in the soil itself.

With respect to possible misunderstandings about the figures contained in the Public Health Service monthly reports on radioactivity in milk, it is important to remember that they should be considered in relation to other figures. The National Committee on Radiation Protection and Measurement, on the basis of the scientific opinion available to it, has set maximum permissible limits for lifetime exposure of the individual to specific radiation and radioactive materials.

These limits were adapted from safety standards for persons working in close proximity to sources of radiation, such as medical X-ray technicians. The occupational permissible limits were divided by 10 to provide permissible limits for the general population.

For strontium-90, for instance, the committee's current recommendation for a maximum permissible concentration is 80 micromicrocuries per liter of water or milk. This means that on the basis of present knowledge the average concentration of strontium-90 among all items of the diet—water, meats, vegetables, bread, and so on—could be 80 micromicrocuries per

liter (or per kilogram—2.2 pounds) for a lifetime without exceeding the current maximum permissible concentration.

(A curie is the amount of radioactivity in 1 gram of radium. A micromicrocurie is one millionth of a millionth of a curie.)

Average yearly levels of radioactivity in milk are far more significant than monthly levels because the yearly averages are more accurately comparable with lifetime permissible limits. For strontium-90, for example, there was an increase in St. Louis, Mo., from 12.2 micromicrocuries in October 1958 to 20.1 in November 1958 (which then dropped back to 15.6 in December). The average level for the year ended October 1958 was 11.4 compared with 12.5 as the average level of the year ended November 1958. This yearly average is to be compared with the 80 micromicrocuries per liter currently used as the lifetime permissible concentration.

I am advised—and it should be emphasized—that these so-called permissible limits are only calculated estimates. They will be subject to change as more and better scientific data are developed about radioactive elements and their effect on the human body.

For example, there has already been some public discussion related to lowering the recommended levels for some elements, such as strontium-90. Further consideration should be given to the amount of strontium-90 which is distributed and retained in the body. A great deal more research is needed to provide data for a more accurate correlation between the amounts found in foodstuffs and their lodgment in the body.

For the time being the current maximum permissible limits represent the most informed scientific opinion available to us.

However, when the total amount of radiation to which people are exposed is increased, measures should be taken to reduce radiation over which we have some control. This led the Public Health Service to advocate several years ago the abolition of X-ray machines used in some stores for fitting shoes, and a year ago the substitution of skin tests for mass X-ray surveys as the first step in detecting tuberculosis.

Last September I discussed at a press con-

under 18. Included were 1,338 children, of whom 568 were under the age of 6, and 770 between 6 and 17.

Coverage

These children do not represent a complete count of the blind children in the State. At least two sources of children known to be blind were not included. A private nursery for blind children in southern California reported that it had 18 children enrolled, and 52 others on its "cradle roll," but refused to permit its medical records to be used for the study. Consideration was given to the inclusion of children in Sonoma, Porterville, and Pacific State Hospitals, and estimates received from the superintendents of these institutions indicate that there are approximately 160 blind children in residence. These were not included partly because it was felt that the primary handicap was not blindness, and also it would have been difficult to obtain complete diagnostic information on a case-by-case basis.

That there may be as many as 200 blind children in the State who are not enrolled in school or known to agencies offering services to preschool blind children was suggested by a review of the records in the department of education. In addition to the 110 children about whom there had been correspondence in 1955 or 1956, there were 229 last discussed in correspondence dated 1954 or earlier. It is difficult to believe that many of these children have died or moved from California. There was evidence that cerebral palsy or mental retardation was present in a fairly high proportion of these cases, and it is possible that some are receiving care in institutions for these conditions. It seems likely that a substantial number of blind children are being cared for at home or in regular schools, without benefit of the specialized training required if they are to become self-sufficient adults.

Even with the exclusions mentioned above, the number of children included in the survey yields rates of blindness considerably higher than those found by previous studies (1, 2). Because of the method used, these rates may be considered to represent minimum estimates of the number of blind children in California.

At least 33 children in every 100,000 were blind, with the rate among preschool children as high as 46 in those 4 years of age (table 1).

The high rates among children 2, 3, and 4 years of age were due to the prevalence of retrolental fibroplasia in that age group. Fortunately, it was discovered that this condition was caused by the use of excessive oxygen for newborn premature infants (3). The establishment of control measures for the administration of oxygen (4) has reduced drastically the incidence of this condition in the 3 years since this survey was made. Recent checks with the two agencies in California concerned with preschool blind children (5) revealed that they were serving 23 children with retrolental fibroplasia who were born in 1955, 9 born in 1956, 1 born in 1957, and so far none born in 1958. It is to be noted that children with retrolental fibroplasia born in the peak years 1951-53 are now reaching school age. Unless their increased number is offset by decreases in blind-

A survey of blind children in California provides basic information for planning programs of prevention.

Blindness in California Children

NEDRA B. BELLOC, M.A., PHYLLIS H. MATTSON, M.S., and
WILLIAM D. SIMMONS, M.P.H.

MAJOR causes of blindness in each age group must be fully explored before preventive efforts can be productive. Planning special educational services for blind children requires a knowledge of the numbers of such children in the population.

In 1954, a prevention of blindness project was undertaken by the California State Department of Public Health. The need to determine the causes of blindness in children and to obtain information on their number and age distribution resulted in this study, done in 1956.

Previous surveys of blind children made by the National Society for the Prevention of Blindness (1, 2) have been limited necessarily to reports from a few cooperating agencies in each participating State. In an effort to make this survey as comprehensive as possible, the prevention of blindness project undertook to gather data about all of the blind and partially sighted children known to school districts with special classes, the State school for the blind, the Variety Club's Blind Babies' Foundation,

and the California State Department of Education.

The staff of the project visited each of the 29 school districts with special classes, transcribing from the medical records data on visual acuity, pathology, etiology, other handicapping conditions, and prognosis, as well as age and sex of each child. Teachers and coordinators were asked whether they knew of other blind children who were not enrolled in the special classes. Such children were included if medical records were available which enabled an assessment of their difficulty either in terms of visual acuity or diagnosis. The Blind Babies' Foundation, a voluntary agency which provides a home counseling and teaching service, supplied similar information for children currently on its rolls. The department of education made available its file on children about whom teachers or parents had inquired. These records were used only if there had been communication about the child during 1955 or 1956 (the 15 months preceding the survey), and sufficient information had been given to establish either or both the visual acuity and diagnosis. Records duplicated from more than one source were eliminated.

Although information was gathered on more than 600 partially sighted children, this report is limited to blind children (those with visual acuity of 20/200 or less in the better eye with maximum correction). Similarly, while records were obtained on a few children over 18 years of age, this report deals only with those

The authors, at the time of the survey, were associated with the prevention of blindness project, a special assignment in the division of preventive medical services, California State Department of Public Health in Berkeley. Mrs. Belloc and Mrs. Mattson were respectively associate statistician and junior public health analyst. Mr. Simmons was supervisor. The project was financed by a grant from the W. K. Kellogg Foundation.

ness due to other causes in the younger ages, we can expect during the next 10 or 12 years, as they move through the school grades, to deal with problems of education for a greatly increased number of blind children.

It is not surprising that most of the children were of school age and attending classes, since the records used in the study were obtained primarily from schools (table 2). The largest group of children (35 percent) were enrolled in so-called sightsaving classes, in which large-print materials are used. Another 25 percent were enrolled in regular classes with work in Braille given by a special teacher. Eighteen

percent attended the resident school for blind children in Berkeley.

Diagnostic information was taken from forms which differed in the various agencies. Many of them did not provide specifically for a description of other handicapping conditions. More than one-half of the records had no information about such conditions. It is therefore probable that the figures shown in table 3 represent an understatement of the number of these conditions present in conjunction with visual impairment. Severe conditions, however, such as mental retardation or cerebral palsy, would be likely to be mentioned if present, and were indicated in almost 10 percent of the records. Seventeen percent of all the children surveyed were known to have one or more handicapping conditions other than blindness.

Causes of Blindness

The diagnostic information given on the medical records was coded according to the Standard Classification of Causes of Blindness recommended by the Committee on Statistics of the Blind, 1956 revision. Since many records showed multiple pathologies, it was necessary to adopt certain arbitrary rules for selecting the one to be coded. Congenital malformations were given preference over infectious conditions, and these in turn were coded before refractive errors or muscular difficulties. Optic nerve atrophy was not coded unless it appeared to be primary. Retrolental fibroplasia was coded as primary regardless of associated or complicating conditions. Nystagmus was coded only if it appeared alone. The etiology was coded with an abbreviation of the standard classification, since the number of cases did not warrant a finer breakdown.

The sites and types of affections of eye conditions are shown in table 4. Since retrolental fibroplasia caused a large proportion of blindness in the younger ages, this table divides the children into groups 5 years of age and younger and 6 to 17 years of age. Nearly three-fourths of the former group were affected by retrolental fibroplasia. Structural anomalies accounted for more than one-quarter of the conditions in the older age group. Retinal

conditions, including retrolental fibroplasia, represented another 25 percent, and affections of the lens, primarily cataracts, totaled 17 percent.

Of more importance from the standpoint of preventive efforts are the causes of blindness shown in table 5. Administration of excessive oxygen was assumed to be the cause of retrolental fibroplasia in 547 children, or 41 percent of the total in all ages. Congenital conditions made up the next largest group, accounting for 14 percent of the preschool group and nearly half of those in the older age group. The etiology was unknown or unspecified in about 15 percent of the cases. It can be safely assumed that many of those for whom no etiology was given had conditions present at birth. If the number of blind children is to be substantially reduced, some way must be found to prevent occurrence of the conditions producing abnormalities in the newborn.

In most of the cases in this study, excluding

retrolental fibroplasia, the actual cause of the blindness was unknown. It was merely reported as present at birth. This is an area in which careful, definitive research in the causes of blindness should be undertaken. Infections of the mother in pregnancy were said to be responsible for a little more than 2 percent of the cases, while infections of the child accounted for 1 percent.

Injuries, other than birth injuries, were responsible for blindness in 28 children, or 2.1 percent of the total. Since these were presumably all preventable, they warrant attention out of proportion to the small number of cases. In nearly 40 percent of the accident cases, the agent was not specified. Of those in which this detail was given, 7 cases, or nearly 30 percent, were due to explosions. Of these, four were boys between the ages of 6 and 10 who were playing with dynamite caps. Falls, including being dropped in infancy, were responsible for 6 cases.

Table 5. Causes of blindness in 1,338 blind children, California, 1956

Unknown or unspecified.....	204	37	167	15.2	6.5	21.7

Tables 4 and 5 were tabulated for the condition in the better eye, which is consistent with the basis upon which the criterion for determination of blindness rests. It was recognized that this may have caused the loss for comparative purposes of a few serious conditions such as neoplasms, in favor of the affection of the better eye which might have a loss of vision due to myopia. A review of the records revealed that there were only 27 cases in which the coding for the two eyes would have been different. The net effect of changes in coding for these 27 cases would have been negligible. Adding the two neoplasms, for example, would have raised the percentage attributed to this cause from 2.8 to 3.0.

Summary

This study was undertaken to determine the causes of blindness among children in California and the number and age distribution of such children. Data were gathered from the medical records available in all school districts with special classes for blind and partially sighted children, the State school for the blind, the State department of education, and the Variety Club's Blind Babies' Foundation. While the coverage is not complete, it is believed that a very high proportion of the total number of blind children in the State is included.

The rate of blindness among children under the age of 18 was found to be 33 per 100,000 with the rate among preschool children as high

as 46 in those 4 years of age. The high rate in the latter group is due to the large number of children born in the years 1951-53 who were blinded by retrolental fibroplasia, a condition found to be due to the administration of excessive oxygen to newborns.

Congenital conditions, primarily of unknown origin, were found to be the cause of a large proportion of blindness in the two age groups studied. A substantial reduction in the number of blind children in future years can only be achieved through the determination of ways to prevent these conditions.

Accidents, which are responsible for a relatively small number of cases, are nonetheless important since it may be possible by the regulation of such hazards as dynamite caps to prevent some tragic cases of blindness in young children.

Economic Poisons Control

CONTROL of economic poisons in manufacturing, agricultural use, the home, and food establishments was the subject of a symposium held during Pennsylvania's seventh annual health conference at University Park in August 1958.

In opening the discussion, Robert C. Stanfill of the Philadelphia District, U.S. Food and Drug Administration, restated today's general regulatory controls, emphasizing these points:

- The estimated death rate from all types of poisoning, solids and liquids, is one-third that of 50 years ago, but the total number of preventable deaths and injuries is still impressive. Negligence on the part of our citizens cannot be prevented solely by legislation.

- Drugs and disinfectants for man and animals are subject to the Federal Food, Drug, and Cosmetic Act of 1938 and its amendments. Under provisions of this act safe tolerances are set for residues of pesticides on crops.

- Pesticides and disinfectants for inanimate objects are controlled by the Insecticide, Fungicide, and Rodenticide Act of 1947.

- Twelve caustic and corrosive acids and alkalis in certain concentrations are designated in the Federal Caustic Poison Act of 1927. Some of these, especially lye which is still used in home laundries and in making soap at home, continue to take their toll of children.

- Many hazardous paints, cleaning compounds, solvents, and miscellaneous agents are not covered by these laws.

- Use of precautionary labels on the 12 household size caustic and corrosive items is required, but adequate labeling of many more items is not covered by law. The incidence of accidental injuries may be reduced by thus identifying composition, harmful potentials, directions for safe use, and methods of emergency treatment.

- Enforcement of the Federal Food, Drug, and Cosmetic Act of 1938 and the Federal Caustic Poison Act of 1927, as amended, is the responsibility of the U.S. Food and Drug Administration. The U.S. Department of Agriculture is responsible for enforcing the provisions of the Insecticide, Fungicide, and Rodenticide Act of 1947 and its amendments. Mailing of certain poisons is controlled by postal laws. Packing specifications and warning regulations on shipping containers of acids, cosmetics, and explosives, are controlled by the Interstate Commerce Commission.

Summaries of other contributions follow.

Manufacturing Hazards

The term "economic poisons" includes a wide variety of chemicals and chemical compounds which have been developed for use in controlling, destroying, or repelling harmful insects or rodents, and predatory animals or other forms of animal life. The term also includes chemical substances used to defoliate plants and hormone-like substances that regulate the growth of plants.

In the production of economic poisons, the manufacturer has responsibilities to his employees and to the community. Successful manufacture and marketing of a product highly toxic to humans requires an industrial medical and hygiene program that insures a healthful working environment for employees. Cyanides and organic phosphate insecticides are among those requiring rigorous safeguards.

The Cyanides

There is a long history of the use of cyanides as fumigants in the control of insects and rodents. Two forms of cyanides are processed at the Warners Plant of the American Cyanamid Company in rather large quantity. One is a solid form which contains approximately 42 percent $\text{Ca}(\text{CN})_2$. The other is commercially pure hydrogen cyanide.

Calcium cyanide, a solid, is milled into various sizes depending on the ultimate use of the product. On exposure to air, it liberates hydrocyanic acid gas. It is essential, therefore, that processing equipment be maintained dusttight: otherwise, dust leaks into the workroom atmosphere lead to hazardous conditions.

The mill employed generates air pressure in the conveyors, elevators, and bins, and it is necessary to remove this pressure. This is accomplished through the use of the exhaust ventilation system. No attempt, however, is made to actually maintain the conveying equipment under a negative pressure since this would increase cyanide losses from the product. This condition of atmospheric balance is assured by a manometer in the ventilating system which is readily adjusted with a slide gate.

The drumming of the milled material is done with the aid of local mechanical exhaust ventilation. This provides an effective dust control and it is possible for the men to fill the drums without resort to gas masks.

Hydrogen cyanide is generated as a gas in reactors and is then condensed to a liquid. It is handled as a liquid from that point. Brine-cooled vessels are used. Here again, the main objective is to prevent the escape of hydrogen cyanide vapor from the equipment into the workroom atmosphere.

Hydrogen cyanide is a lethal gas and pre-

cautions must be observed wherever it is handled. At room temperature, it is a liquid but will boil at 79° F. With such a low boiling point, it is quite volatile and its vapor can penetrate all crevices and spaces to bring about the complete fumigation of the area being treated. Hydrogen cyanide gas is not irritating and, therefore, to the uninformed the potentially hazardous nature of an exposure may not be immediately apparent. This is true because the gas can be tolerated at concentrations that are dangerous. The gas is easily recognized by its odor which is like that of bitter almonds. The effect of HCN, in either gas or liquid form, is that of a chemical asphyxiant.

Hydrogen cyanide produces its toxic action with extreme rapidity. It is thought that hydrogen cyanide inactivates certain enzymes that catalyze oxidative processes in the tissues. Asphyxia at cellular level results from the arrest of the oxidative process. It is, in effect, a protoplasmic poison.

The essential health hazard in its processing is from inhalation. Absorption through the lungs is rapid. It can also be absorbed through the skin. If the skin is broken, or irritated, absorption is more rapid. The American Conference of Governmental Industrial Hygienists has established a maximum allowable concentration of 10 parts of hydrogen cyanide per million parts of air for daily exposures of 8 hours.

The symptoms following exposure to small quantities are headache, giddiness, fatigue, loss of appetite, and nausea. Rapid and complete recovery takes place upon removal from these small exposures. With greater exposure, additional symptoms may occur: sense of suffocation, vertigo, cyanosis, coma, convulsions, and death.

The greatest potential for escape of gas in our manufacture occurs from the reactors and from sampling points. Exhaust ventilation is employed rather extensively at the packings around the agitator bearings and at the sampling points, the entire system being connected to a water spray scrubber which prevents the discharge of hydrogen cyanide to the outdoors. The water is returned to the process to reclaim the cyanide collected.

The crude hydrogen cyanide is distilled and

stabilized, whereupon it is ready for packaging in compressed gas cylinders or as cyanide impregnated woodpulp disks. As a liquid, the material is handled quite safely although it is essential to maintain continued vigilance and care. Even small drops spilled on the floor can serve as a source of exposure to operators. These must be avoided.

Because hydrogen cyanide cannot be permanently stabilized, it is important that all cylinders be returned to the factory within 6 months of the filling date. This is necessary even though none of the hydrogen cyanide in the cylinder has been used. If allowed to stay in the cylinders indefinitely, the product may decompose. The accompanying heat and pressure may be sufficient to cause the cylinder to explode with possible loss of life and property.

Parathion

A major development in the growing list of economic poisons has been the manufacture of organic phosphate insecticides. One of the more toxic of the organic phosphates is parathion.

Parathion, when absorbed into the body, causes an inhibition of the enzyme cholinesterase and thereby allows the accumulation of large amounts of acetylcholine. As the cholinesterase levels are reduced, grave signs and symptoms may appear. These do not develop until the cholinesterase activity has been reduced to about 50 to 25 percent of normal. However, symptoms can also occur with a much smaller depression, provided it is rapid. The symptoms include headache, blurred vision, weakness, nausea, abdominal cramps, diarrhea, and tightness in the chest. The signs may include sweating, miosis, tearing, pulmonary edema, cyanosis, convulsions, coma, loss of reflexes, and respiratory muscle paralysis. Atropine, in excess of amounts conventionally employed, oxygen, and artificial respiration are used in the treatment of parathion poisoning. Lacking such treatment, death may result. The development of sensitive laboratory tests for the determination of cholinesterase levels in the blood has been most helpful in maintaining a continuous knowledge of the degree of exposure created by manufacturing operations. It is reported that new antidotes are

being developed for poisoning from this substance and they may offer improved treatment.

We have encountered little difficulty in the manufacture of parathion as a result of vapor exposures from the product. The most serious exposure hazard is the possibility of liquid parathion being absorbed through the skin. This exposure may occur from a small spill which may not be noticed immediately, since technical parathion is not a primary irritant. It is necessary to insist that operators take a complete shower at the end of each workday. Freshly laundered, complete work-clothing outfits are supplied the men daily by the company. Separate lockers are provided for street clothing and work clothing. Eating in the workroom is prohibited, and a separate lunchroom, removed from the operating area, is maintained.

The same emphasis on mechanical exhaust ventilation is given in the manufacture of parathion as in the cyanides. There is little danger of significant vapor exposure since the vapor pressure of parathion is relatively low at ambient temperature.

Medical control is maintained through periodic blood testing to determine cholinesterase levels of the employees, in addition to the mechanical aids to prevent exposure.

Maintenance workers must be safeguarded. Used piping and drums must be decontaminated. The prevention of exposure extends also to the control laboratory where a similar program of good industrial hygiene is maintained.

Employee Education and Deportment

All employees are thoroughly indoctrinated in the potential health hazards involved in processing economic poisons. This is done to establish a feeling of confidence so they will know how to act in any emergency.

Casual visits to these departments are not encouraged, even by employees of the plant.

The location of all persons in the department must be known at all times since, in an emergency, we want to be immediately assured they are safe. There is no time for delay in starting rescue efforts. A "buddy" system has been established, each employee being required to know the whereabouts of his partner at all times.

These precautionary methods have been very effective over the many years of manufacturing experience at our Warners Plant. On rare occasions, there have existed some temporary conditions of emergency but good deportment of the men on the job has prevented fatal accidents.

The attention given to conserving the health of men engaged in the manufacture of these economic poisons has been worthwhile. However, the manufacturer has a slight advantage in health conservation over the user. The manufacturer has a fixed installation, a group of trained chemical operators, and the availability of technical services. The user does not have a fixed installation in many cases and the training of his sprayers may be more on the basis of instilling fear rather than confidence.

In addition to technical services and literature offered by all manufacturers and the information contained on all of the warning labels of products, it is considered desirable that health agencies continue to direct their efforts toward good health practices in the manufacture and use of economic poisons.—JOSEPH F. MELLOR, JR., *industrial hygienist, Warners Plant, American Cyanamid Co., Linden, N.J.*

Food Establishment Use

Economic poisons most frequently used in food establishments are insecticides and rodenticides.

Many employ professional pest control operators experienced in the application of economic poisons and aware of the dangers from careless use of such poisons. On the other hand, proprietors of smaller food establishments may do their own pest control work.

If pest control efforts are confined to the use of registered insecticides and the instructions on the container are followed carefully, there will be little hazard of food contamination. A real danger exists, however, if insecticides and rodenticides not recommended for use in food establishments are purchased and applied in a careless manner.

As in the past, it is important to emphasize sanitation, screening, and ratproofing to re-

duce infestations by insects and rodents. Observance of such measures results in a minimum and more effective use of insecticides and rodenticides.

The use of economic poisons in food establishments has become more complex as many new pesticides have been developed. Formerly, pyrethrins, rotenone, organic thiocyanates, and sodium fluoride were the chief insecticides. Compounds of phosphorus, arsenic, thallium, and red squill were rodenticides commonly used. After World War II, many chlorinated hydrocarbon insecticides, some organic phosphate compounds, pyrethrum synergists, allethrin, and anticoagulant rodenticides appeared on the market.

These newer pesticides vary greatly in their toxicity to warmblooded animals, and some of the more toxic ones are not recommended for use in areas where food is prepared.

The importance of reading and following the directions on the labels of pesticides cannot be overemphasized. The consumer's ignorance on this subject was emphasized in a recent survey undertaken by the Chemical Specialties Manufacturers Association entitled "Do People Read Labels on Household Insecticides?" The survey showed that only between 8 and 15 percent of the people using these products were aware of the important precautions required for many years on all aerosol and liquid spray labels.

Hazards in the use of insecticides by inexperienced individuals are increased by ignorance of the cautions on labels.—ARNOLD MALIS, *Gulf Research and Development Co., Pittsburgh, Pa.*

Agricultural Residues

Our primary concern today is the unintentional chemical additives whose number is expanding at a rapid rate. Unintentional additives include pesticide residues, residues of antibiotics and hormones used for growth stimulation, traces of chemicals that cannot be avoided in good manufacturing practice, as well as residues of drug products resulting from the medication of animal feeds.

Of these, pesticide residues are the object of widespread attention. The modern history of pesticide residues began with the advent of DDT during World War II. Since then, a number of new organic materials, many of them quite specific, have been developed.

Pesticides, by definition, are those substances which prevent, destroy, repel, or mitigate insects, rodents, and other forms of undesirable plant or animal life. In actual practice, destruction is the most common method of control.

This killing is accomplished by substances poisonous to the particular form of life. Very often these substances are deleterious to higher forms of life, including man.

Resultant illnesses in man can be classified as either chronic or acute, depending on either a high or low level of toxic material and duration of exposure. For most substances, the effect of a high level of toxicity is well established, but there is great concern and a considerable lack of knowledge regarding the toxicology of low levels. There are many unanswered questions regarding the safety of small residues appearing in food.

As examples, lindane is not recommended for use on calves under 3 months of age, on milk cows, or on animals within 30 days of slaughter. It is used, however, in electric vaporizers for fly control in restaurants and considered safe insofar as the patron is concerned. What of the waitress or busboy who works in the dining room 8 or more hours a day? We can all recall pictures of Italian and North African children being dusted with DDT for typhus, yet recently several carloads of spinach were destroyed in Chicago because of an excessive DDT residue.

Probably the most important steps forward in controlling pesticides have been those resulting from the Miller Amendment to the Federal Food, Drug, and Cosmetic Act whereby approximately 100 chemicals have been cleared for food protection and more than 1,500 individual tolerances have been established on the basis of scientific data to permit these chemicals to be used effectively and safely for the benefit of farmers and consumers alike.

The number of chemicals and individual tolerances so identified increase with every re-

lease by the Food and Drug Administration. These tolerances are in the range of 0.1 to 14 ppm for the most part. One percent is the equivalent of 10,000 ppm so these tolerances are rather small. Certain chemicals are exempt from tolerances, and for a few a zero tolerance has been set, which means that they cannot be used under conditions leaving any toxic residue whatsoever.

A series of antibiotics and hormones have been developed that stimulate growth either by direct action on the animal or plant or by the repression of bacteria, parasites, or other organisms. A majority of animal feeds today contain penicillin, chlortetracycline, or tetracycline at a level of less than 50 grams per ton, and many feeds contain a considerably higher amount.

Use of an antibiotic on raw poultry up to 7 ppm is becoming almost routine in many large processing plants. Cooking effectively destroys this chemical additive. Hormones, such as diethylstilbestrol, are fed to many steers as a part of the daily ration, although in some cases ear implants are used to supply the hormone.

The liberal use of antibiotics in humans for minor conditions is thought by some to limit their effectiveness in a real emergency. How much of a buildup is obtained a few parts per million at a time from milk and from other sources is difficult to determine.

Residues resulting from the incorporation of drugs into animal feed, especially poultry feed, appear to present no acute problems.

It is evident that control of agricultural residues requires a combination of education and cooperation, with emphasis placed on the following points. The grower must follow directions for use in both the time and rate of application, discontinuing use prior to harvest as indicated. The processor must accept only those raw agricultural commodities that fall within specified tolerances, following good manufacturing practices to reduce the amount of residue. The meat producer must stop the use of medicated feeds prior to slaughter. The dairy farmer must discard milk immediately following mastitis treatment. The baker and ice cream manufacturer must use only acceptable stabi-

These precautionary methods have been very effective over the many years of manufacturing experience at our Warners Plant. On rare occasions, there have existed some temporary conditions of emergency but good deportment of the men on the job has prevented fatal accidents.

The attention given to conserving the health of men engaged in the manufacture of these economic poisons has been worthwhile. However, the manufacturer has a slight advantage in health conservation over the user. The manufacturer has a fixed installation, a group of trained chemical operators, and the availability of technical services. The user does not have a fixed installation in many cases and the training of his sprayers may be more on the basis of instilling fear rather than confidence.

In addition to technical services and literature offered by all manufacturers and the information contained on all of the warning labels of products, it is considered desirable that health agencies continue to direct their efforts toward good health practices in the manufacture and use of economic poisons.—JOSEPH F. MELLOR, JR., *industrial hygienist, Warners Plant, American Cyanamid Co., Linden, N.J.*

Food Establishment Use

Economic poisons most frequently used in food establishments are insecticides and rodenticides.

Many employ professional pest control operators experienced in the application of economic poisons and aware of the dangers from careless use of such poisons. On the other hand, proprietors of smaller food establishments may do their own pest control work.

If pest control efforts are confined to the use of registered insecticides and the instructions on the container are followed carefully, there will be little hazard of food contamination. A real danger exists, however, if insecticides and rodenticides not recommended for use in food establishments are purchased and applied in a careless manner.

As in the past, it is important to emphasize sanitation, screening, and ratproofing to re-

duce infestations by insects and rodents. Observance of such measures results in a minimum and more effective use of insecticides and rodenticides.

The use of economic poisons in food establishments has become more complex as many new pesticides have been developed. Formerly, pyrethrins, rotenone, organic thiocyanates, and sodium fluoride were the chief insecticides. Compounds of phosphorus, arsenic, thallium, and red squill were rodenticides commonly used. After World War II, many chlorinated hydrocarbon insecticides, some organic phosphate compounds, pyrethrum synergists, allethrin, and anticoagulant rodenticides appeared on the market.

These newer pesticides vary greatly in their toxicity to warmblooded animals, and some of the more toxic ones are not recommended for use in areas where food is prepared.

The importance of reading and following the directions on the labels of pesticides cannot be overemphasized. The consumer's ignorance on this subject was emphasized in a recent survey undertaken by the Chemical Specialties Manufacturers Association entitled "Do People Read Labels on Household Insecticides?" The survey showed that only between 8 and 15 percent of the people using these products were aware of the important precautions required for many years on all aerosol and liquid spray labels.

Hazards in the use of insecticides by inexperienced individuals are increased by ignorance of the cautions on labels.—ARNOLD MILLIS, *Gulf Research and Development Co., Pittsburgh, Pa.*

Agricultural Residues

Our primary concern today is the unintentional chemical additives whose number is expanding at a rapid rate. Unintentional additives include pesticide residues, residues of antibiotics and hormones used for growth stimulation, traces of chemicals that cannot be avoided in good manufacturing practice, as well as residues of drug products resulting from the medication of animal feeds.

Patients Served by a Mental Health Unit of a City Health Department

JACOB TUCKMAN, Ph.D., and MARTHA LAVELL, M.S.S.

THE RECOGNITION of the public health aspects of mental illness has led to the establishment of mental health units by an increasing number of public health departments. Such units perform many functions which vary in scope and emphasis with the needs of the community and the degree of public support. These functions may include planning and coordination of mental health services, consultation to public and private agencies, inservice training, mental health education, casefinding, surveys, research, and direct services to individuals with mental health problems. Such direct services are usually limited to children but may include adults and special groups such as alcoholics.

Little is known about the characteristics of patients who come to the attention of mental health units of public health departments. The purpose of this study, therefore, was to obtain certain information about individuals known to the division of mental health of the Philadelphia Department of Public Health during the period 1955-57, its first 3 years of operation. Although there are gaps in the data, such material may be useful to health departments contemplating the establishment of mental health units or to already established units as a basis for comparison.

The services provided by the division, available to anyone in the community, include diag-

nostic evaluation and psychiatric treatment of children, adolescents, and adults; and consultation, information, and referral services directly to the patient or to responsible relatives, interested individuals, or agencies acting on his behalf. In selected cases, psychiatric evaluation and treatment on a continuing basis are available to individuals in their own homes.

Patient Data

During the 3-year period the division served 1,734 persons. Information about these patients was obtained from the case record, frequently limited to pertinent material noted on a 5- by 8-inch card. Data about the characteristics of the patient had not been gathered routinely because contact with the patient or a responsible relative was for brief periods or was limited to telephone contacts or because of the pressures on an overburdened staff. The material collected from the records was coded and transferred to punched cards.

Of the 1,734 individuals studied, 39 percent were male and 61 percent female. A breakdown by race shows 37 percent were white, 22 percent nonwhite, and 41 percent whose race was not stated. Since the proportion of nonwhites in the Philadelphia population has been estimated to be 24 percent (1), it seems probable, considering the large number of those whose race was not stated, that nonwhites were over-represented in the patient population.

The number of patients served varied with place of residence. Using 1957 estimated population figures for Philadelphia (1), rates were calculated for the 10 health districts into which the city is divided. They varied from 19.2 to

Dr. Tuckman is chief, section on psychological services, education, and standards, division of mental health, Philadelphia Department of Public Health, and associate in psychology in psychiatry, School of Medicine, University of Pennsylvania. Miss Lavell is statistician with the division of mental health.

lizers and emulsifiers. The confectionary maker must use only Food and Drug Administration certified colors. The food industry in general must exercise self-discipline with regard to chemical additives and pesticide residues. And the consumer must insist on adequate labeling and become more label conscious.—DELMAR K. MYERS, *Pennsylvania State Department of Agriculture*.

Home Control Activities

Limitations to current preventive measures hamper the control of accidental poisonings in the home. Some of the limitations and their solutions are:

- The tendency to categorize such accidents into groups, such as occupational, motor vehicular, and home, is conducive to duplication and overlapping of effort. Coordination among official and unofficial organizations, permitting the breakdown of artificial groupings and a free flow of information, is a "must."

- A standardization of language in the total field rather than a special jargon for each grouping is needed.

- To depend entirely on mortality data is a mistake. Morbidity data must also be collected and taken into account.

- One of the first educational efforts should be directed to eliminating "luck" as a so-called "cause" of accidents. The definite sequence of events that ends in an accident should be emphasized, showing that the negation of one of the factors in a sequence will prevent or modify the seriousness of an accident.

To date, accident preventers have attempted to accomplish their job primarily through the use of mass educational techniques. Mass edu-

cation is valuable when used to create a philosophy or community awareness of the problem. It is my thought, however, that it does not cause many individuals to change their living habits or their environment. The most lasting and rewarding results will come through specific educational efforts, tailoring the message to meet the needs of small reference groups. Scheduling of periodic meetings of such small groups should be developed to revive and maintain the impact of accident prevention drives.

Historically, the control of poisonings in Pennsylvania received its initial impetus from the American Academy of Pediatrics which formed an accident prevention committee early in 1950, resolving to urge its affiliates to undertake accident prevention activities.

In 1956, the Pennsylvania Department of Health joined with the Pennsylvania Academy of Pediatrics in establishing poison treatment centers in the State's hospitals. An accident prevention unit was formed in the Philadelphia Department of Health the same year, instituting a poison information center for round-the-clock emergency service to the public. A follow-up procedure is based on home accidental poisoning cases reported to this center. A public health nurse visits the victim's home to investigate and report the cause of the accidental poisoning.

A morbidity reporting system based on hospital reports of treated accidental injuries will be put into operation shortly by the Pennsylvania Department of Health. A trained investigator will follow up these reports to explore the "how" and "why" of accidental injuries. Accidental poisonings are to be included.—DAN D. GOWINGS, M.P.H., *director, division of environmental safety, Pennsylvania Department of Health*.

Table 2. Percentage of patients served by the division of mental health, Philadelphia, 1955-57, according to referral source

Referral source	Under 18 years (N=256)	18-64 years (N=1,061)	65 years and over (N=398)	Total ¹ (N=1,734)
Medical facilities:				
Health department	43	7	5	12
General hospitals and clinics	8	11	8	10
Psychiatric hospitals and clinics	4	4	3	4
Out-of-State psychiatric hospitals	0	1	1	1
City and State agencies (excluding medical):

Not stated	(2)	5	4	4

¹ Includes 19 cases not classifiable by age.

² Less than 0.5 percent.

NOTE: $\chi^2=406.60$; $df=20$; $P<.001$ (for the χ^2 analysis, psychiatric hospitals and clinics were combined with out-of-State psychiatric hospitals; other interested persons were combined with schools).

unions, Federal agencies (Army recruiting station, Bureau of Old-Age and Survivors Insurance, Housing Redevelopment and Relocation), chamber of commerce, American Legion, and others.

Significant age differences were found with respect to referral source. Health department referrals accounted for 43 percent of those under 18 years compared with 7 percent of those between 18 and 64, and 5 percent of those 65 and older. These findings were not unexpected in view of recent program developments in the division focusing on preschool

children seen in child health conferences at local health centers. Referrals from law enforcement agencies also accounted for a higher proportion of those under 18 years than of those in the two categories of adults, probably because such agencies are more likely to use community resources for children and adolescents than for adult offenders. Persons 65 and older were more likely than the other age groups to be referred by State agencies other than hospitals (primarily the department of public assistance), and persons between 18 and 64 years were most likely to be referred by voluntary welfare agencies.

The difficulties for which help was sought covered a wide range. Among the children were some who were not developing normally or who presented other problems of management, others with difficulties in school adjustment, and still others who had had a brush with the law.

The adults presented psychiatric problems of varying degree. In some cases the psychiatric problem contributed to marital difficulties. Some patients exhibiting paranoid tendencies appeared periodically at the mayor's office of information and complaints, at the police department, and at other public and private agencies demanding restitution or protection. Other mentally ill persons created public health or fire hazards by throwing garbage out of windows or accumulating trash. Some created a public nuisance by quarreling with or taunting their neighbors. In some cases the mentally ill person constituted such a potential danger to himself or to others that it was necessary in the absence of a responsible relative or interested agency to petition the court for psychiatric examination.

Some patients were public assistance clients for whom the agency requested evaluation of mental competency because there was a question about their ability to handle funds. Many patients were older persons who presented a variety of problems involving an impairment of their ability to maintain themselves economically, psychologically, physically, and socially.

One small group of patients in the most urgent need of hospitalization had been placed in jail because of the shortage of hospital beds. This practice has been terminated through

160.5 per 100,000. Health districts with high rates tended to be areas with high mortality and delinquency rates, substandard housing, and low income. Three percent of the total group resided outside of Philadelphia.

Only a very small percentage of the patients (7 percent) were without a responsible relative. Almost three-quarters (72 percent) had one or more close relatives, but this did not always mean that the relatives were willing or able to assist them. In 21 percent of the cases no information was available regarding the existence of a relative.

The age distribution of the patients ranged from a few weeks to 96 years (table 1). Of the total group, 11 percent were under 15 years, 7 percent between 15 and 24, 23 percent between 25 and 44, 18 percent between 45 and 64, and 19 percent 65 years of age and over.

In 22 percent of the cases, the actual age of the patient was not stated, but it was possible to estimate from the case record the age of most of these patients: 4 percent were children, 73 percent were adults, and an additional 21 percent were known to be older adults. For purposes of analysis, these cases were combined with those with ages specified in the following manner: children without a specified age were considered to be under 18 years; adults were considered to fall within the 18- to 64-year age range; and older adults were considered to be 65 or older.

Such an age grouping seemed reasonable in view of the special problems of children and the aged, both of whom tend to be dependent upon others for their agency contacts. Com-

parisons with general population figures for Philadelphia showed that children were under-represented (15 percent in the patient population and 27 percent in the general population), adults were about equal (62 percent and 65 percent, respectively), and older adults were over-represented (23 percent and 8 percent, respectively).

There were significant differences between the sexes in the age distribution. The children included 10 percent of the females compared with 18 percent of the males; the older adults, 19 percent of the males compared with 26 percent of the females.

Sources of Referral

Patients were referred to the division through many different channels, representing 87 unduplicated types of referral source (table 2). Twenty-seven percent were referred by medical sources, such as various divisions of the health department, general hospitals and clinics, and psychiatric hospitals and clinics.

Nonmedical city and State agencies referred 25 percent: 10 percent from such sources as the mayor's office of information and complaints, department of public welfare, licenses and inspection, personnel department, commission on human relations; 7 percent from law enforcement agencies such as courts, district attorney's office, police department including the juvenile aid bureau, and prisons; and 8 percent from State agencies such as the department of public assistance, department of welfare (bureau of aging services, bureau of hospitals, and State council for the blind), bureau of rehabilitation, and the board of parole.

Fourteen percent were referred by voluntary agencies concerned with child care and protection, financial assistance including shelters, nursing services, employment, rehabilitation, legal aid, and services for special groups such as the blind, prisoners, and transients. In 15 percent of the cases, the patient was referred by himself or his family. Eleven percent were referred by various interested persons including friends, neighbors, politicians, councilmen, lawyers, and landlords. Four percent were referred by miscellaneous sources including private nursing homes, employers, churches, labor

in 18 percent from 1 to 5 months, and in 5 percent for 5 months or more. Persons receiving service for at least 5 months were more likely to be children.

Outcome of contact with the patient is shown in table 5. Thirty-three percent of the cases were closed after information had been given regarding psychiatric resources or procedures, or after a referral had been made to a specific community resource, contacted by the division for this purpose. Five percent of the patients were referred to ancillary resources such as nursing homes and family, employment, and group work agencies. Seven percent of the patients were advised that a community resource which had previously served them would be more helpful to them.

Sixteen percent of the cases were closed after service had been completed for the public or private agency currently active in the situation. Most of these cases involved consultation and advice in meeting the patient's psychiatric

problem, but in some cases a supplementary service was performed, such as a home visit to determine mental competency.

In 13 percent of the cases, the patient or family refused help; in another 8 percent, the patient or family or both, were encouraged to seek psychiatric help, but the record contained no information that they had done so. Two percent of the cases were closed after the division had petitioned the court for psychiatric examination. In 14 percent no further contact was required for various reasons; the patient had shown improvement through extended casework or through individual or group psychotherapy, had died, disappeared, been sent to jail, had broken contact, or did not present a psychiatric problem.

There were significant age differences with respect to outcome of contact. A higher proportion of children than adults or older adults refused help; while a higher proportion of both adult groups than children was given information about psychiatric resources and procedures.

Discussion

Although the 1,734 patients served by the division of mental health during the first 3 years of operation included persons of all ages, children were under-represented and older adults over-represented by comparison with general population figures. The reason for this fact was that much of the work of the division in its early years was necessarily devoted to meeting the needs of chronic patients, since facilities in the community for the care and treatment of the mentally ill were inadequate. With the development of new programs and increased facilities, however, there has been a reduction in the backlog of mentally ill persons with unmet needs, making possible a greater emphasis on preventive work with children.

It might be expected that the major channel of contact for patients would be through the private and public health and welfare organizations. However, more than 40 percent of the patients came to the division through other sources, and almost all of these were appropriate referrals. This suggests a considerable degree of sophistication on the part of lay per-

new program. A small number of patients had recently been discharged from a mental hospital and needed help with employment, housing, social contacts, or psychiatric care on an outpatient basis. In a few cases social history data were required by a State hospital to help in planning for the patient or determining whether the home was ready to receive him.

Contacts and Outcome

The type of contact with the patient is shown in table 3. In half the cases (48 percent) contact with the patient or on his behalf was by telephone or correspondence or both; such contacts included information, referral, and consultation services. These contacts were not necessarily of short duration, since extensive exploration was often necessary to locate the appropriate community resource. In 24 percent of the cases, patients were interviewed in the division's offices or in health centers, usually by a psychiatric social worker but also by a psychiatrist or psychologist. Office contacts demanded more intensive work in clarifying the problem and in helping the patient and family accept referral for psychiatric help.

In 21 percent of the cases, visits to the pa-

tient's home were necessary, usually by psychiatric social workers, but in some cases by a psychiatrist, whose medical opinion was required regarding the mental competency of the patient. In some cases it was necessary for both psychiatric social worker and psychiatrist to make the home visit. In 2 percent of the cases, contact included diagnostic psychological testing or individual or group psychotherapy, or both, with or without a home visit.

There were significant age differences in type of contact. Home visits were required most for older adults, less for younger adults, and least for children. By contrast, such services as diagnostic psychological testing and psychotherapy were limited almost entirely to children, reflecting program emphasis.

There were also significant differences between the sexes in type of contact. Twenty-four percent of the women compared with 15 percent of the men required home visits.

Length of contact with the patient varied from 1 day to more than 5 months (table 4). The 1-day contacts generally were limited to telephone calls or an office visit. The longest contacts were with patients requiring more extensive psychiatric casework assistance or psychotherapy on a continuing basis. In 50 percent of the cases, contact with the patient lasted less than 1 week. In 20 percent of the cases contact was maintained from 1 week to 29 days,

An annual report in a series begun by the Communicable Disease Center in 1955, summarizing the findings of its nationwide surveillance activities.

Arthropod-Borne Encephalitis in the United States, 1957

JACOB A. BRODY, M.D., and WALTER A. MURRAY, Jr., M.D.

ENCEPHALITIS virus activity decreased in 1957, according to reports from epidemiologists of 46 States to the Communicable Disease Center, Public Health Service. Eastern encephalitis (EE) epizootics occurred in the Gulf States and as far north as South Carolina, but only five confirmed human cases came to our attention: two in Florida and three in Louisiana (fig. 1). Minimal virus activity was recorded in New Jersey and Massachusetts.

Western encephalitis (WE) virus activity was prominent only in the Mountain States in 1957, with California and Texas registering few cases (fig. 1). The majority of the reported human cases were centered about a small outbreak in the Denver, Colo., area.

The major public health problem in 1957 among the arthropod-borne diseases in the United States continued to be St. Louis encephalitis (SLE), with the bulk of cases in

Texas and California (fig. 1). Florida registered its first proved case, the only geographic extension of the North American arthropod-borne encephalitides beyond previous historical limits (1). The sizable outbreak of SLE occurring in the lower Rio Grande Valley appears to be the only major concentration of human cases of encephalitis in 1957.

Data Collection

Since 1955 information has been collected from State and local health departments, medical and veterinary virus diagnostic laboratories, the Disease and Eradication Division of the U.S. Department of Agriculture, and other sources.

Most of the appraisal of the 1957 data was carried out by the epidemiologists, laboratory directors, and public health veterinarians in State health departments. The National Office of Vital Statistics of the Public Health Service gave statistical advice, and cooperation was afforded by virus laboratories of several academic institutions, the National Institutes of Health Rocky Mountain Laboratory at Hamilton, Mont., the Walter Reed Army Institute of Research, Washington, D.C., and the Fourth U.S. Army Medical Laboratory in Dallas, Tex. Continued mutual exchange of data in 1957 resulted in four concurrent seasonal reports

Dr. Murray serves as assistant chief of the Surveillance Section, and Dr. Brody as intelligence service officer assigned to that section in the Epidemiology Branch of the Communicable Disease Center, Public Health Service, Atlanta, Ga. Dr. Alan W. Donaldson, assistant chief of operations, and Dr. Mario Pizzi, chief of the Surveillance Section at the Center, aided in the compilation of the data; and Ida L. Sherman, of the Center's Statistics Section, gave statistical assistance.

sons and organizations in recognizing psychiatric problems.

The study presents useful information about some characteristics of patients served by a mental health unit. Unfortunately, there were gaps in data on race, religion, marital status, and occupation. Although more information was available for patients seen face-to-face than for those served by telephone or correspondence, the gaps in data on the former group were too great to permit statistical analysis. In-

formation on the factors previously mentioned and others such as income, amount of schooling, mobility, and previous psychiatric care is essential for a better understanding of the patient load, and for program planning and improvement of services.

Career Opportunities

Columbia University and the Institute for Crippled and Disabled will conduct a work conference June 8-26, 1959, on the roles of medicine, counseling, psychology, and social work in a vocationally oriented rehabilitation center. The conference is supported by a grant from the Office of Vocational Rehabilitation, Department of Health, Education, and Welfare. Enrollment is limited to professional workers in the field of rehabilitation.

Yale University Department of Public Health offers for the academic year 1959-60 a new program designed to prepare nurses for positions in supervision, education, and consultation in chronic illness nursing. Funds for the course were made available through the Connecticut State Department of Health by a graduate training grant from the National Heart Institute of the Public Health Service.

The program covers a minimum of one academic year for students with advanced experience and training and leads to the degree of master of public health with a major in chronic illness nursing. Admission requirements include a bachelor's degree, graduation from an approved school of nursing, and experience in public health or teaching.

The University of Minnesota School of Public Health offers the second annual workshop on air pollution July 6-17, 1959.

Designed for engineers, physicians, chemists, and sanitation personnel concerned with community air pollution from the educational, governmental, or industrial viewpoint, the course will consist of lectures, demonstrations, field trips, and the application of fundamental knowledge in solving the air pollution problem

of a community. Enrollment is limited to 25. Applications may be filed with the University's School of Public Health, 1325 Mayo Memorial Building, Minneapolis 14, Minn.

The University of Minnesota has also announced a summer continuation course of instruction in chronic diseases, July 27 through August 22, 1959. The course is presented with the cooperation of the schools of public health of the United States and the Conference of Chronic Disease Training Program Directors as a non-academic-credit program in chronic diseases on the graduate level for physicians in health agencies and research workers in the medical sciences.

Subject areas are epidemiological methods in noninfectious diseases, recent advances in experimental and clinical aspects of heart disease and cancer, and public health chronic disease control programs with emphasis on heart disease.

Further information may be obtained by writing to Dr. Leonard M. Schuman, Professor of Epidemiology, School of Public Health, at the university.

Teachers College, Columbia University, will hold a work conference on the sheltered workshop as a community resource in the vocational rehabilitation of mentally retarded adolescents and adults July 27 through August 14, 1959, under the sponsorship of the Association for the Help of Retarded Children, Inc.

Information may be obtained from Dr. Abraham Jacobs, Box 35, Department of Psychological Foundations and Services, Teachers College, Columbia University, New York 27, N.Y.

and an annual summary report, which form the basis of information for this presentation.

Eastern Encephalitis

Five confirmed human cases of eastern encephalitis paralleled the reported occurrence of cases in horses in both early seasonal occurrence and geographic distribution, with the exception of an unusually early onset (February) in one of the two cases in Florida (table 1). The Florida patients recovered with very severe sequelae, whereas two patients in Louisiana recovered completely, but a third in that State was the only death reported. A presumptive case of EE was reported from McCracken County, Ky., in an 8-year-old girl who recovered, with persistent hemiparesis.

Information from the southern States revealed a prolonged seasonal incidence among horses, confirmed cases occurring from May through September. The clinical course of the disease in affected horses was characteristically violent, terminating in death in 24 to 48 hours. In all, 28 virus isolations were made from horse brains submitted to four laboratories from five States (table 2).

Ecological studies in Baldwin County, Ala., yielded the only virus isolation from mosquitoes in 1957 (2). A small endemic focus was suggested by isolations of virus from a number of species of wild birds and mosquitoes over a period of several months.

In contrast with 1955 and 1956, EE in pheasants was rare. The disease was evident in one captive pheasant flock in southern New Jersey in late September. One virus isolation was made. Although no reported cases in horses and pheasants occurred in Massachusetts, evidence of minimum virus activity was indicated in study areas by virus isolations from one wild and two sentinel pheasants, and the presence of antibodies in immature chickens, turkeys, starlings, and swine. From this area, the first human biting record for *Culiseta melanura* in a natural setting was established in September 1957 (3).

Similar ecological studies were conducted in Florida, Georgia, and South Carolina. In Georgia and South Carolina, antibodies were demonstrated in wild birds and immature feral swine, although no virus was isolated from mosquitoes, small mammals, or fowl. Negative

¹ Reported Incidence of Notifiable Diseases in the United States, 1957, Morbidity and Mortality Weekly Report, Annual Supplement, vol. 7, No. 53, National Office of Vital Statistics, Public Health Service.

² One confirmed case and two presumptive cases of St. Louis encephalitis.

³ Confirmed.

In several States large numbers of mosquito pools, primarily *Culex tarsalis*, were examined for virus. Most investigators processed pools of 50 mosquitoes.

The results reported for 1957 by the California State Department of Public Health are compared with results in the State for other years, where similar techniques in collection were used (4):

Isolations	1954	1955	1956	1957
Pools tested.....	989	1,113	1,047	920
Pools positive.....	238	82	145	93
WE virus.....	151	68	143	44
SLE virus.....	87	14	2	49

Some 65 pools of *C. tarsalis* were positive for WE in collections from the Denver and Greeley areas. From 5 to 20 pools were positive among those tested from Texas, Idaho, North Dakota, and Washington. All isolations were from pools of *C. tarsalis* except the pools of *Culex quinquefasciatus* from Cameron County, Tex.

Western encephalitis made a late seasonal appearance in the region of Baldwin County, Ala., where eastern encephalitis is known to be endemic. In late October and November, three isolations were made from pools of *C. melanura* and three from wild birds.

St. Louis Encephalitis

After an interval of 2 years, SLE returned during 1957 in epidemic force to the Rio Grande Valley of Texas. The disease occurred for the second consecutive year in the high plains region also, but to a much lesser extent.

The outbreak in Cameron County, Tex., with some 119 clinical cases, was fairly classic for SLE. The area is semitropical, with an unusually large wild bird population. After a period of heavy rains, a long drought provided ideal conditions for the emergence of numerous *C. quinquefasciatus* mosquitoes. Cases began occurring around mid-July, reaching a peak during the last week in July and the first week in August. By the end of the month no new cases were being reported.

The attack rate was 160 cases per 100,000 inhabitants for the entire area, with considerable local variations. Harlingen was the major

urban center affected. The attack rate there was about 140 per 100,000.

The distribution by age and sex did not differ from other SLE epidemics in this area east of the Rockies. Cases occurred in all age groups, with the greatest concentration between 21-40 years of age (51 cases), but the highest attack rate occurred among persons over 60. The large number of men between 21-40 years who became ill is partially explained by the age distribution of the population which is affected by the proximity of an Air Force base and the employment of numerous braceros. There were three deaths: two men, ages 60 and 84, and one woman, age 86. A total of 42 cases were serologically confirmed in two laboratories as SLE by fourfold or greater rise in complement fixation antibody.

During the outbreak, control measures were instituted by State, local, and military and other Federal agencies. These were directed principally toward a large-scale dusting campaign, using a 3 percent gamma isomer of benzene hexachloride ($C_6H_6Cl_6$).

In California, confirmation of 23 cases of SLE from 11 counties was reported. The age distribution of the patients was quite similar to that in previous years, with eight below age 10 and nine over age 30. This distribution is higher than for WE in this area, where more than two-thirds of the cases are in infants and children, but lower than for SLE cases occurring east of the Rockies, where more than two-thirds were in adults. Virus isolations from *C. tarsalis* pools revealed 49 recoveries, as compared with 2 in 1956.

In Colorado, where SLE predominated in 1956, only four cases were confirmed, but these were of unusual interest as all but one occurred in infants, paralleling the age pattern in the larger WE epidemic in that State. Four confirmed cases were registered in Kentucky, two of which occurred in Jefferson County, the site of a sizable urban outbreak in 1956. Perhaps even more significant was a single case from Clayton County, Mo., which is the first proved case, to our knowledge, in the St. Louis area in many years. There was also a strongly presumptive case in Illinois.

The single case of SLE that occurred in Florida in a 21-year-old man was unique. It

antibody and viral findings from a study in Florida are equally important epidemiologically.

Western Encephalitis

About 40 confirmed human cases of WE occurred in 1957, as in each year since 1955, when routine surveillance of encephalitis began. For the first time, however, the majority of cases emanated from a single epidemic, a small outbreak in Denver, Colo. Data from minor foci,

which cover a more restricted geographic area than in previous years, are presented in table 1.

About half of the human cases that occurred in Colorado were in the Denver area. Cases occurred from mid-July to the first of October. Although more than 100 clinical cases were reported, laboratory confirmation was obtained for only 22. The age pattern of these confirmed cases conforms closely to the national experience over recent years, with almost 50 percent of the cases occurring in infants (table 3).

¹ One case was presumptive.

The disease in horses was concentrated mainly in an area extending from the northwestern corner of Utah up through Idaho to the western portions of Oregon and Washington. Very few human cases were noted in these areas. Sporadic cases also occurred in the Dakotas, Montana, Wyoming, and Nevada.

Although close surveillance of encephalitis was continued in California in 1957, only three cases of WE were confirmed and one of these possibly originated outside the State (4). One of the patients, a 3-year-old boy, became ill on March 23, which is the earliest known date of onset recorded in the State.

Since WE is not particularly lethal to horses, virus isolations are infrequent. All confirmed cases in horses in 1957 were proved by serologic methods; they occurred in California, Colorado, Oklahoma, Utah, Washington, Wisconsin, Oregon, Arizona, and Mississippi.

In several States large numbers of mosquito pools, primarily *Culex tarsalis*, were examined for virus. Most investigators processed pools of 50 mosquitoes.

The results reported for 1957 by the California State Department of Public Health are compared with results in the State for other years, where similar techniques in collection were used (4):

Isolations	1954	1955	1956	1957
Pools tested-----	989	1,113	1,047	920
Pools positive-----	238	82	145	93
WE virus-----	151	68	143	44
SLE virus-----	87	14	2	49

Some 65 pools of *C. tarsalis* were positive for WE in collections from the Denver and Greeley areas. From 5 to 20 pools were positive among those tested from Texas, Idaho, North Dakota, and Washington. All isolations were from pools of *C. tarsalis* except the pools of *Culex quinquefasciatus* from Cameron County, Tex.

Western encephalitis made a late seasonal appearance in the region of Baldwin County, Ala., where eastern encephalitis is known to be endemic. In late October and November, three isolations were made from pools of *C. melanura* and three from wild birds.

St. Louis Encephalitis

After an interval of 2 years, SLE returned during 1957 in epidemic force to the Rio Grande Valley of Texas. The disease occurred for the second consecutive year in the high plains region also, but to a much lesser extent.

The outbreak in Cameron County, Tex., with some 119 clinical cases, was fairly classic for SLE. The area is semitropical, with an unusually large wild bird population. After a period of heavy rains, a long drought provided ideal conditions for the emergence of numerous *C. quinquefasciatus* mosquitoes. Cases began occurring around mid-July, reaching a peak during the last week in July and the first week in August. By the end of the month no new cases were being reported.

The attack rate was 160 cases per 100,000 inhabitants for the entire area, with considerable local variations. Harlingen was the major

urban center affected. The attack rate there was about 140 per 100,000.

The distribution by age and sex did not differ from other SLE epidemics in this area east of the Rockies. Cases occurred in all age groups, with the greatest concentration between 21-40 years of age (51 cases), but the highest attack rate occurred among persons over 60. The large number of men between 21-40 years who became ill is partially explained by the age distribution of the population which is affected by the proximity of an Air Force base and the employment of numerous braceros. There were three deaths: two men, ages 60 and 84, and one woman, age 86. A total of 42 cases were serologically confirmed in two laboratories as SLE by fourfold or greater rise in complement fixation antibody.

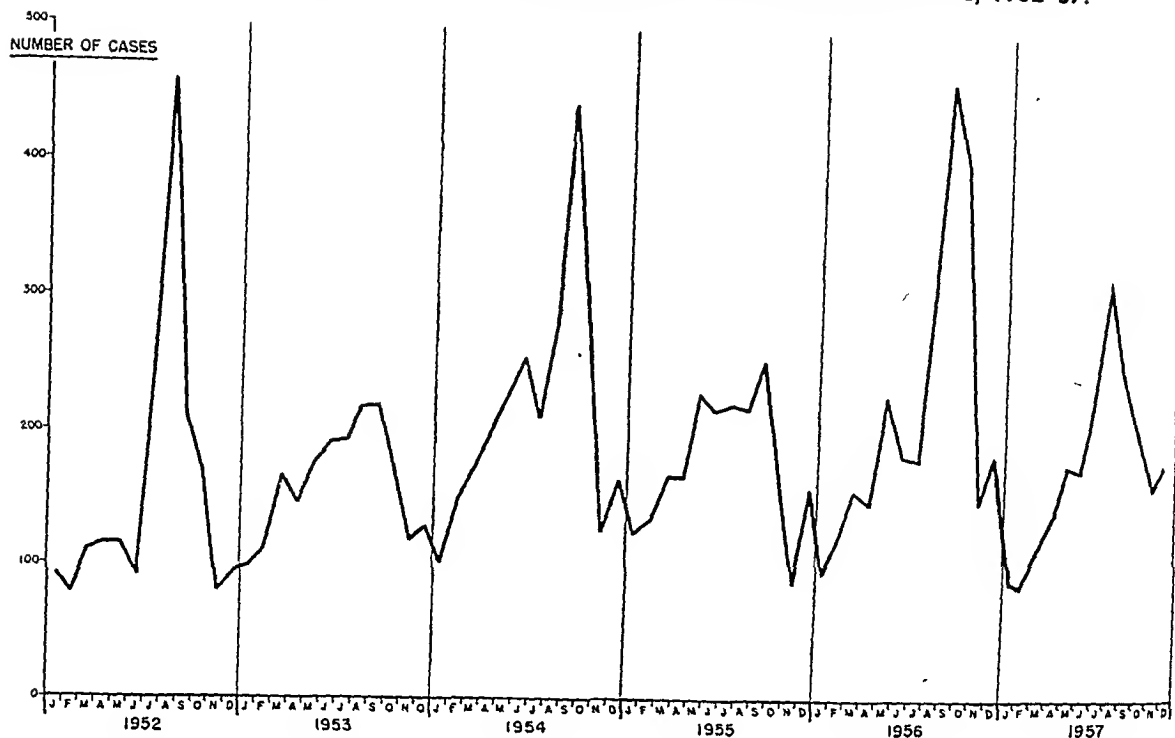

During the outbreak, control measures were instituted by State, local, and military and other Federal agencies. These were directed principally toward a large-scale dusting campaign, using a 3 percent gamma isomer of benzene hexachloride ($C_6H_6Cl_6$).

In California, confirmation of 23 cases of SLE from 11 counties was reported. The age distribution of the patients was quite similar to that in previous years, with eight below age 10 and nine over age 30. This distribution is higher than for WE in this area, where more than two-thirds of the cases are in infants and children, but lower than for SLE cases occurring east of the Rockies, where more than two-thirds were in adults. Virus isolations from *C. tarsalis* pools revealed 49 recoveries, as compared with 2 in 1956.

In Colorado, where SLE predominated in 1956, only four cases were confirmed, but these were of unusual interest as all but one occurred in infants, paralleling the age pattern in the larger WE epidemic in that State. Four confirmed cases were registered in Kentucky, two of which occurred in Jefferson County, the site of a sizable urban outbreak in 1956. Perhaps even more significant was a single case from Clayton County, Mo., which is the first proved case, to our knowledge, in the St. Louis area in many years. There was also a strongly presumptive case in Illinois.

The single case of SLE that occurred in Florida in a 21-year-old man was unique. It

Figure 2. Reported infectious encephalitis cases in the United States, 1952-57.

is the first report of this disease entity in the State and the first diagnosis made by virus isolation from cerebrospinal fluid. Isolation of SLE virus from body fluids has been successful only once previously, in 1946 from peripheral blood (5).

Indicative of a persistent low level of SLE virus activity in other areas were isolations of the virus in pools of unengorged *C. tarsalis* mosquitoes in North Dakota, Idaho, Colorado, and Washington. A pool of engorged *Culex pipiens* mosquitoes collected from a chicken coop in the vicinity of two human cases in Bullitt County, Ky., provided further verification of virus activity in that area.

National Case Reporting

The monthly incidence of acute infectious encephalitis in humans for 1957 has been compiled from weekly morbidity reports submitted by States to the National Office of Vital Statistics. Comparison with corrected final monthly totals of reported cases for recent years indicates a lower third quarter peak for 1957

than for 4 of the past 5 years (fig. 2). This total represents all reported cases of post- and para-infectious encephalitis and lymphocytic choriomeningitis along with the arthropod-borne encephalitis. Although many cases in 1957 reported as encephalitis were later shown to be aseptic meningitis, the total of 2,135 cases is below that of the previous 3 years. In 1956 the figure was 2,624. Table 1 gives figures of acute encephalitis by State, as well as confirmed cases and deaths from arthropod-borne encephalitis.

The 1,525 cases in horses, with 639 deaths reported by States to the U.S. Department of Agriculture (6), was the largest number of encephalitis cases in equines reported since 1953 (table 2). As for the past 3 years, about one-half of the reports on horse cases were from the east coast, where there are proportionately smaller numbers of horses. This may be partially a reporting artifact since EE prevalent in the area is 90 percent fatal and therefore well reported. The milder course of western encephalitis in horses, as reflected by a low case fatality rate, may fail to stimulate reporting of this dis-

ease in large horse populations of the western United States.

Discussion

Control and ultimate eradication of arthropod-borne encephalitis is dependent to a large extent on the gradual accumulation and interpretation of information. While few human cases occurred in 1957, the viruses were widely dispersed throughout nature. By means of active surveillance, certain general trends and findings have become apparent.

Only five cases of EE appeared in humans in 1957, while a large epizootic occurred among horses in the Gulf States. Human cases were confined to Florida and Louisiana. Only one death occurred among these cases, which is consistent with the finding that this disease is somewhat milder in the Gulf States than in Massachusetts, the other major area of concentration of EE cases.

Evidence is accumulating that *C. melanura* is the most important vector in the avian-mosquito cycle of EE. Whether this mosquito is the vector for human cases is not clear, although the first human biting record for *C. melanura* in nature was obtained during 1957.

As would be expected in a mosquito-borne disease, weather apparently influenced virus activity. From North Carolina northward very little rain fell during 1957 and there was almost no virus activity. A major epizootic, however, occurred along the Gulf. In 1956, when rain was plentiful in New England, the virus was considerably more prominent.

While most of the human cases of WE were centered about the Denver area, horse cases and virus isolation from birds and mosquitoes clearly indicate that this disease is very widespread in nature. Cases in humans continue to occur predominantly among infants. Evidence from studies in California (7) indicates that younger cases are most likely to have sequelae. When one considers that an increasing area in the United States comes under irrigation each year and that the extremely efficient vector *C. tarsalis* is becoming more abundant, the magnitude of the potential hazard of WE is demonstrated.

Since the first epidemic of SLE in St. Louis

in 1933, this disease has appeared periodically in epidemic form. The epidemic in Cameron County, Tex., in 1957 was typical of the disease. SLE virus, like that of WE, occurs widely throughout nature.

The factors maintaining these viruses in nature and the sudden precipitation of epidemics are being studied intensively. One fact which seems to be emerging is that large epidemics of SLE are preceded by periods of heavy rain, followed by drought. This cycle apparently favors the breeding of the major vector *C. quinquefasciatus-pipiens*, which breeds best in still water with a high concentration of inorganic salt and organic materials.

Investigations continue on the mechanism of overwintering of the virus and the biology of the mosquito vectors. The possible role of mammals as hosts for the virus and the migratory pattern of birds and their nesting habits in relationship to virus activity are also being studied. In the laboratory, levels of viremia of possible hosts and their infectivity for possible vectors are being elucidated. In the field, the value of predicting epidemics by periodic collection of mosquitoes for virus isolation and regular bleeding of sentinel birds to detect the introduction of the virus into an area are being tested, while the prognostic use of meteorological data such as ground and air temperature and rainfall are under investigation. The problems are varied and diffuse, but experience in 1957 slowly brings us a step closer to the goals of effective control of arthropod-borne encephalitis.

Summary

During 1957, surveillance of arthropod-borne encephalitis revealed fewer cases of the diseases than for the previous year among humans and more plentiful cases among horses. The only major epidemic was an epidemic of SLE in Cameron County, Tex. Five cases of EE in humans were reported, and an epizootic among horses occurred along the Gulf States. Human cases of WE were centered about the Denver area, while the sum of virus activity in man, animals, birds, and mosquitoes, for both SLE and WE, was widely distributed throughout the country. SLE continued to be the ma-

for public health problem among the arthropod-borne encephalitides, with the epidemic occurring in Texas and confirmed cases occurring in six other States.

Several advances toward ultimate control of these diseases were made by better understanding of host and vector potentialities and the influence of meteorological conditions on viral spread.

Anticancer Drug Development

For the first time, a pharmaceutical firm has been contracted by the Public Health Service to develop, test, and manufacture antibiotics and related drugs for the treatment of cancer. The award, which runs until the end of 1959, was made by the Service's Cancer Chemotherapy National Service Center at the National Cancer Institute, to the Upjohn Co. of Kalamazoo, Mich.

Drugs found safe in research by the company will be evaluated in clinical trials under the direction of the service center. If the results indicate the drugs are of real value, the company is obligated to undertake their production.

Terms of the contract are in line with the new patent policy of the Department of Health, Education, and Welfare, which permits a contractor to patent and sell drugs or other chemical agents developed under contract with the Government. However, if the manufacturer fails to supply adequate quantities to meet the public need, the Surgeon General of the Public Health Service may license other firms to produce the drug.

publications

Health Statistics From the U.S. National Health Survey. Hospitalization: patients discharged from short-stay hospitals, United States, July 1957-June 1958. *PHS Publication No. 584-B7; 1958; 40 pages; 30 cents.*

Estimates of discharges and hospital days, percentage distributions, rates per 1,000 persons per year, and average length of stay are shown for four major characteristics: age, sex, hospital ownership, and type of hospital service.

The report also presents data dealing with socioeconomic variables, length-of-stay intervals, conditions for which the patients were hospitalized, and number and type of surgical cases. Appendixes carry technical notes on methods and give definitions of terms.

Salaries of State Public Health Workers, August 1958. *PHS Publication No. 647; 1958; 41 pages.*

Data in this report, taken from State and Territorial health department payrolls, include salaries of health officers, program directors, and various occupational groups.

Graphs and tables show distributions by State or by Bureau of the Census region.

Social Security Programs Throughout the World, 1958. *Social Security Administration Publication (Unnumbered); 1958; 115 pages; \$1.*

Intended to provide complete and up-to-date information, this report summarizes social security programs, including financial provisions, in 78 countries. It discusses old-age, invalidity, survivors, health, maternity, unemployment, and work injuries insurance as well as family allowance and other related programs.

The material, supported by 93 pages of charts, was drawn primarily from foreign laws or authoritative translations. It was supplemented by foreign service dispatches of the

Department of State and publications of the International Labor Office, the International Social Security Association, and social security agencies of foreign countries. Many of the summaries have been approved by social security officials in the countries concerned.

Proceedings, 1958 Annual Conference, Surgeon General, Public Health Service and Chief, Children's Bureau, With State and Territorial Health Officers. *PHS Publication No. 653; 1959; 56 pages.* Includes remarks and addresses by the Secretary, Department of Health, Education, and Welfare, the Surgeon General, Public Health Service, the Chief, Children's Bureau, and the Chief, Division of Special Health Services, Bureau of State Services. Presents recommendations on Federal relations, environmental sanitation, infectious disease, hospitals and medical services, long-term illness and health of the aging, Indian health, and migrant labor. Contains resolutions adopted by the Association of State and Territorial Health Officers.

More Than Bread. *Social Security Administration Publication (Unnumbered); 1958; by Helen C. Manning; 24 pages; 15 cents.*

Directed to community leaders, civic groups, and others interested in community welfare, this booklet describes social services in public assistance. It offers suggestions for community projects designed to increase understanding and support of social services.

Vignettes are used to show responsibilities shared by public welfare agencies and the community for helping needy people. The results achieved through social services are highlighted in reports of projects conducted in several States.

In addition to copies for sale by the Superintendent of Documents

(see note below) free copies in limited quantities may be obtained from the Office of the Assistant to the Director, Bureau of Public Assistance, Social Security Administration, Washington 25, D.C.

Reported Tuberculosis Data. Calendar year 1956. *PHS Publication No. 638; 1959; by Lawrence W. Shaw and Paul L. Roney; 25 pages; 25 cents.*

This fifth annual summary presents data supplied to the Public Health Service on the Annual Tuberculosis Report by the States and Territories. The data cover newly reported tuberculosis cases for each State by source of morbidity report, activity status, form and extent of the disease, race, sex, and age as well as X-ray casefinding activities and mortality.

Summary tables present United States totals for the years 1952 through 1956, and accompanying text points out pertinent characteristics inherent in the data.

Better Teeth for Life—Fluoridation. *PHS Publication No. 636; 1958; 16 pages; 15 cents.*

This popularly written booklet tells the story of the research that led to fluoridation of public water supplies. It also outlines the seriousness of the dental health problem and summarizes the progress of fluoridation in this country and abroad.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared with Federal support.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Office of Information, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

Signs

and

Symptoms

of trends in public health

Radiation from some luminous watches is "several times greater than natural background radiation and exceeds by more than 100 times that presently received from radioactive fallout," reported G. D. Chase and A. Osol in the October 1958 issue of *Science*.

In 5 years, they found, one is subjected to a dose of 5 rem; the International Commission of Radiation Protection recommends no dose in excess of 5 rem by age 30.

" "

Local SS Medical Institute, a new medical center in St. Louis, Mo., financed with health and welfare funds of the Meat Cutters Union, Local 88, was dedicated in October, during the 86th APHA conference.

" "

National Science Foundation says survey of 127,000 American scientists showed that three out of four know at least one foreign language. Only about 2 percent have some knowledge of Russian, and 1 percent know Chinese or Japanese.

" "

The division of sanitary engineering, Pennsylvania Department of Health, has published a pamphlet entitled, "Your Clean Streams Program."

" "

Dr. Charles S. Cameron, dean, Hahnemann Medical College, has called for a permanent national commission to recommend and coordinate medical research and indicate the relative emphasis to be placed in each field. It should be possible, he says, to agree reasonably on the relative importance of, say, cerebral palsy and better teeth.

The North Carolina State Board of Health has issued a 527-page, indexed volume on Public Health and Related Laws of North Carolina.

" "

Twenty new medical schools would have to be added to the 87 now existing or planned if the 1955 ratio of 131.9 physicians per 100,000 population is to be maintained in 1975, G. St.J. Perrott and M. Y. Pennell report in the *Journal of Medical Education*, September 1958. They also point out that the Association of American Medical Colleges has advocated the establishment of new 2-year schools of basic medical sciences as a means of increasing the enrollment of third-year classes of existing medical schools by 400 students each year.

" "

Forty-five State health departments now recognize accident prevention as a public health responsibility and engage in some degree of activity; 13 departments have a full-time accident prevention staff of one or more persons.

" "

About 50 million people suffer "accidental" injury yearly, the National Health Survey, Public Health Service, reports after a 6-month study. About 40 percent are injured at home, 17 percent at work, and 10 percent by motor vehicles. The remaining 33 percent suffer accidents from other causes, including those in public places during recreation.

" "

Automobile Safety is a new, 8-page, quarterly, published by the Automobile Manufacturers Association.

A manual entitled "Emergency Childbirth" has been written by Dr. Gregory J. White, and published by the Police Training Foundation, Franklin Park, Ill.

" "

Britons, in addition to their government's free medical service, now can buy medical insurance which includes the services of family physicians.

" "

With the aim of discovering clues to prematurity and malformations at birth, the University of Pittsburgh Graduate School of Public Health has received \$60,000 from the National Institutes of Health, Public Health Service, and the Association for the Aid of Crippled Children to study methods of obtaining accurate, scientifically useful information from pregnant women. Two hundred women from the Pittsburgh area will be asked questions on their daily eating habits, physical activity, and characteristic symptoms.

" "

The British Occupational Hygiene Society is organizing an international symposium on Inhaled Particles and Vapors for April 1960. Those wishing to contribute papers should notify W. H. Walton, Worton Hall, Worton Road, Isleworth, Middlesex, England.

" "

Use of closed-circuit TV for training and instruction in science may be enhanced by Eidophor, a device which projects an image in color on a screen wider than 13 feet. The instruments promise advantages in resolution, definition, and color fidelity.

" "

The Atomic Energy Commission has announced a plan (subject to hearing) to license a Texas corporation to collect and prepackage low-level radioactive waste, encase it in reinforced concrete, and sink it at least 6,000 feet in the Gulf of Mexico about 180 miles south of Galveston, beyond the Continental Shelf. It is presumed that, even if the packages break, the radioactivity of surface water would not rise above permissible levels.

The Nation's first clearly established case of rabies infection in a human from a bat's bite was reported in December 1958 by the California State Health Department.

" "

The Atomic Energy Commission announced in November 1958 that it will report to the public on radiation accidents which took place in plants operating under licenses from the Commission. The Commission also plans to publicize special reports from licensees on safety matters.

" "

A program of integrated training for law and medical students in Massachusetts is being set up with the assistance of Professor William J. Curran, Medical Research Institute, Boston University. The training will help physicians become better witnesses in court and help lawyers to conduct questioning with better understanding of medicolegal cases.

" "

Maternal mortality rate in this country has declined 93 percent in the last four decades—from 1 death in 165 live births in 1915 to 1 death in approximately 2,300 live births today.

" "

For the first time, a serial research publication, entitled "Wildlife Disease," is being issued in microfilm. The first copy appeared in January 1959. Original manuscripts are printed on 3" x 5" cards. A maximum of 47 pages of text are printed on each card. No more than one article appears on a card.

" "

Highway fatalities declined in 1958 for the second consecutive year. In 1957 there were 1,100 fewer highway fatalities than in 1956 when a record of 39,600 was set. In 1958 fatalities declined another 1,500 to 37,000.

" "

Vitamin preparations are the subject of a comprehensive report by the American Medical Association Council on Foods and Nutrition, published in full in the January 3, 1959, issue of the *Journal of the American Medical Association*.

Twelve home accident prevention seminars, sponsored by the Tennessee Department of Public Health, were held in a number of counties in that State during 1958. Exhibits, informational materials from insurance companies, and films accompanied talks and discussions.

" "

The Army has developed an emergency medical packet for use in treating mass casualties, civilian or military. It will be used by all three services. The packet has 23 items and medical material adequate to care for 100 casualties in 72 hours. The container is light and inexpensive, easily identified by color or symbol, and may be sealed against tampering. It is easily carried by one person.

A countywide glaucoma and diabetes screening survey was conducted in rural Graham County in western Kansas during April 1958. Of the 593 persons over 40 years of age screened for glaucoma, 23 were referred for further examination. Eleven of those referred were diagnosed as having the disease. Of the 694 persons over 35 years of age tested for diabetes, 22 were found to be positive.

" "

Fellowships in human ecology and its relation to health have been established by Cornell University Medical College. Inquiries should be addressed to Dr. E. Hugh Luckey, New York Hospital-Cornell Medical Center, 525 East 68th St., New York 21, N.Y.

State police conducted rigid carbon monoxide detection tests on 8,000 school buses throughout Pennsylvania during August 1958. Buses with even a trace of carbon monoxide were held for special inspection of the exhaust system.

Air samples from the front and rear of buses were taken with a

hand-held instrument equipped with a sensitive detector tube (see illustration). If carbon monoxide is present, the contents of the tube turn green. The amount of carbon dioxide present is indicated by the intensity of color, which is compared with a color scale mounted beside the tube.

RPR testing projects have been established in the five border reception centers at El Paso, Hidalgo, and Eagle Pass, Tex., Nogales, Ariz., and El Centro, Calif., by the Division of Foreign Quarantine to screen all braceros on a routine, year-round basis. The RPR test has also been used successfully in demonstration projects in Cook County Jail in Chicago and with migrant groups in North Carolina and Arizona.

selected for comparison with the RPR test because they represented a slide flocculation, tube flocculation, and a complement fixation test with cardiolipin antigens and a test using treponemal antigen.

To obtain sufficient reactive specimens for a valid comparison of these tests, approximately one-half the sample was drawn from persons reactive to the rapid plasma reagin test, the other half from those who were nonreactive.

Results

In the total group of 47,579 braceros tested, the RPR test was nonreactive in 90.4 percent, weakly reactive in 1.4 percent, and reactive in 8.2 percent. The corresponding percentages for the sample group of 1,672 specimens were 45.8 percent nonreactive, 6.3 percent weakly reactive, and 47.9 percent reactive (table 1). The ratio of weakly reactive to reactive was 1:5.9 in the total group and 1:7.6 in the sample. Among the other four tests performed on the sample, the VDRL slide test obtained the highest percentage of nonreactive results (55.7); and the TPCF test, the lowest (35.5).

A comparison is made in table 2 of the results of the rapid plasma reagin test with corresponding results of the VDRL, Hinton, Kolmer, and TPCF tests in 1,604 specimens giving definite results to all tests. Among 747 specimens nonreactive to the RPR test, almost parallel nonreactive results are seen with the VDRL slide test (99.5 percent), Hinton (99.1 percent), and Kolmer (98.4 percent). The TPCF test shows least agreement, with only 69.2 percent nonreactive. The 103 specimens weakly reactive to the RPR test were 77.7

diagnosed as pinta. Eight workers had previously received adequate treatment for syphilis and 130 could not be located.

Those workers for whom treatment was indicated received 2.4 million units of benzathine penicillin G as a single 4-cc. intramuscular injection. All but two in the primary and secondary stage were discovered as lesion suspects by the Foreign Quarantine personnel in their routine health examination, demonstrating the effectiveness of this inspection, and were confirmed as darkfield-positive by the special project physician assigned by the Venereal Disease Branch.

Methods

In order to compare the performance of the RPR test to several other blood-testing procedures, a total of 1,672 blood specimens from braceros previously tested by the RPR test at El Centro were shipped to the Venereal Disease Research Laboratory at Chamblee, Ga., where the VDRL slide, Kolmer cardiolipin complement fixation, Hinton flocculation (2), and *Treponema pallidum* complement fixation (3) tests were performed. These tests were

Table 1. Total sample of 1,672 specimens from El Centro, Calif., by test result

Test	Nonreactive		Weakly reactive		Reactive		Anticomplementary		Not tested	
	Number	Percent	Number	Percent	Number	Percent	Number	Percent	Number	Percent

VDRL	932	55.7	143	8.6	591	35.3			6	.4

Table 2. Comparison of RPR test with VDRL, Hinton, Kolmer, and TPCF tests in 1,604 specimens from El Centro, Calif., giving definite results to all tests (anticomplementary and not tested excluded)

Result of other tests	VDRL slide		Hinton flocculation		Kolmer cardiolipin		TPCF	
	Number	Percent	Number	Percent	Number	Percent	Number	Percent
747 specimens nonreactive to RPR								
Nonreactive.....	743	99.5	740	99.1	735	98.4	517	69.2
Weakly reactive.....	1	.1	1	.1	2	.3	119	15.9
Reactive.....	3	.4	6	.8	10	1.3	111	14.9
103 specimens weakly reactive to RPR								
Nonreactive.....	80	77.7	54	52.4	38	36.9	5	4.9
Weakly reactive.....	16	15.5	11	10.7	14	13.6	16	15.5
Reactive.....	7	6.8	38	36.9	51	49.5	82	79.6
754 specimens reactive to RPR								
Nonreactive.....	93	12.3	33	4.4	25	3.3	64	8.5
Weakly reactive.....	125	16.6	24	3.2	12	1.6	135	17.9
Reactive.....	536	71.1	697	92.4	717	95.1	555	73.6

percent nonreactive to the VDRL, 52.4 percent nonreactive to the Hinton, and 36.9 percent nonreactive to the Kolmer test. Only 4.9 percent of these specimens were nonreactive to the TPCF test.

Of the 754 specimens reactive to the RPR test, the greatest agreement is with the Kolmer test, with 95.1 percent reactive and only 3.3 percent nonreactive; agreement is also close with the Hinton test, in which 92.4 percent of the specimens were reactive and 4.4 percent nonreactive. Oddly enough, the VDRL slide and TPCF tests, at opposite extremes in reactivity in specimens nonreactive and weakly

reactive to the RPR test, have approximately the same reactivity rates, 71.1 and 73.6 percent, respectively among specimens reactive to the RPR. When weakly reactive and reactive results are combined for each of the compared tests, total reactivity ranges from 96.7 percent for the Kolmer to 87.7 percent for the VDRL in the group of 754 specimens reactive to the rapid plasma reagin test.

The actual percentage of agreement between the RPR and the other compared tests in these 1,604 specimens is shown in table 3. Complete agreement is defined as both tests nonreactive, both tests weakly reactive, or both tests reac-

Table 3. Percentage of agreement between RPR and other tests in 1,604 specimens from El Centro, Calif., giving definite results to all tests

Other tests	Complete agreement		Partial agreement		Disagreement	
	Number	Percent	Number	Percent	Number	Percent
Kolmer	1,466	91.4	63	3.9	75	4.7
Hinton flocculation.....	1,448	90.3	62	3.8	94	5.9
VDRL slide.....	1,295	80.7	132	8.2	177	11.1
TPCF.....	1,088	67.8	217	13.6	299	18.6

tive. A reactive result to one test and weakly reactive result to the other is considered partial agreement. The RPR was in complete agreement with the Kolmer test in 91.4 percent of the specimens and with the Hinton in 90.3 percent. Complete agreement is lowest when the RPR is compared with the TPCF test, 67.8 percent. Disagreement with the rapid plasma reagin test ranges from 4.7 percent for the Kolmer to 18.6 percent for the TPCF test.

In order to determine the type of specimens in which the majority of discrepancies occurred, the results of the TPCF test are compared with the results of the RPR and VDRL quantitative slide test (fig. 1). The general pattern of this chart—an increase in percentage of specimens reactive to the TPCF test with increasing reactivity of the RPR and VDRL slide tests—is broken by the second bar which represents specimens which were weakly reactive to the RPR and nonreactive to the VDRL test. In this group, 80 percent were reactive to the TPCF test and only 3.8 percent were nonreactive. Among 743 specimens which were

Figure 1. Result of TPCF test compared with results of RPR and VDRL tests.

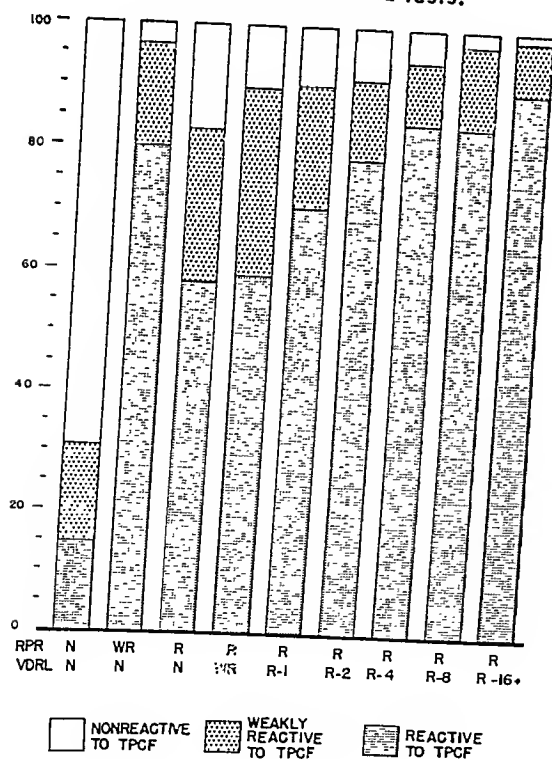

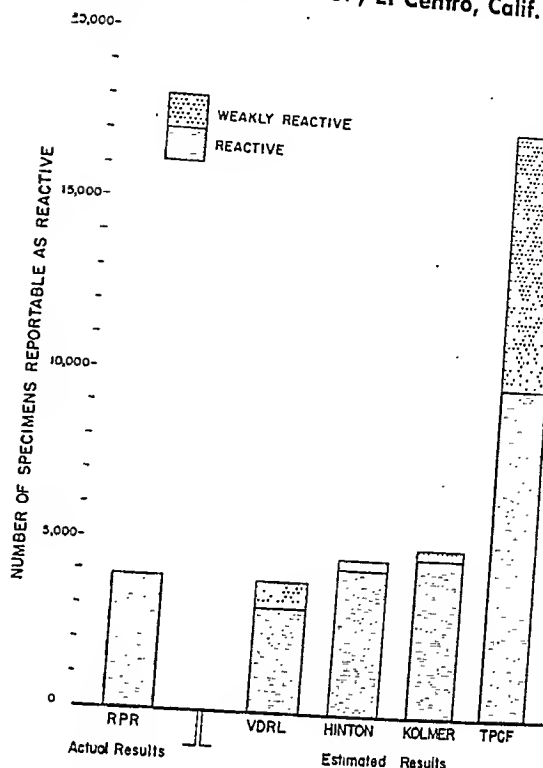

Figure 2. Actual reactivity of RPR test and estimated reactivity of other tests among 47,579 braceros tested in 1957, El Centro, Calif.

nonreactive to both the RPR and VDRL tests, more than 3 out of every 10 specimens showed some reactivity to the TPCF (14.5 percent reactive and 16 percent weakly reactive). Although this latter observation would indicate greater sensitivity of the TPCF test, among specimens reactive to the RPR, the percentage nonreactive to the TPCF ranged from 17.2 percent when the VDRL was nonreactive to 1.3 percent when the VDRL was reactive to 16 or more dil.

On the basis of the results obtained in the sample, estimates have been made of the number of specimens that would have been reportable (reactive or weakly reactive) in the Kolmer, Hinton, VDRL slide, and TPCF tests, had these tests been performed on the total 47,579 specimens. Only the reactive results of the RPR test are reported to the physician at the bracero reception center laboratories, whereas both reactive and weakly reactive results of the other tests are reportable. Therefore, consideration was given to these practices in preparing the estimate for comparison of

these several testing procedures. These estimates are compared with the actual number of specimens that were reactive to the RPR test (fig. 2).

As opposed to the figure of 3,913 specimens (8.2 percent) that were reactive to the RPR test, 3,865, or 8.1 percent, would have been reactive or weakly reactive to the VDRL slide test; 4,547, or 9.6 percent, to the Hinton; 4,948, or 10.4 percent, to the Kolmer; and 17,452, or 36.7 percent, would have been reactive or weakly reactive to the TPCF test. (The TPCF technique employed in this evaluation was found to have a high reactivity and a low specificity in the SERA study (4) and has since been modified by the test's authors.) The actual number of specimens reactive to the RPR test most closely approximates the number of reportable reactions for the VDRL slide test.

Discussion

The group of specimens under consideration was highly selective, being taken entirely from Mexican male laborers with an unknown percentage of associated pinta, and selected on the basis of the result of the RPR test (roughly one-half reactive, one-half nonreactive). The results reported here may differ considerably from results obtained in a random sample of the population. In this series, however, the result of the RPR test agreed closely with the results of the Kolmer cardioliipin and Hinton flocculation tests.

Summary

During the period April 16 through June 28, 1957, a total of 47,579 Mexican agricultural workers were tested with the rapid plasma reagin test at El Centro, Calif. Reactive re-

sults were obtained in 3,913 and weakly reactive results in 685, a total reactivity rate of 9.7 percent.

In this same period a sample consisting of 1,672 specimens from workers tested by the RPR test was subjected to a battery of tests, including the VDRL slide, Kolmer cardioliipin complement fixation, Hinton flocculation, and TPCF, at the Venereal Disease Research Laboratory.

The Kolmer and the Hinton tests were in closest agreement with the RPR test, the percentage of complete or partial agreement being 95.3 and 94.1, respectively. Least agreement was obtained with the TPCF test, 81.4 percent. The TPCF test showed some reactivity in 3 out of every 10 specimens which were nonreactive to both the RPR and VDRL slide tests.

If one of these other tests had been used in place of the RPR at the El Centro reception center, it is estimated on the basis of the sample that reactive or weakly reactive results would have been obtained by the VDRL slide test in 3,865, by the Hinton in 4,547, by the Kolmer in 4,948, and by the TPCF in 17,452 specimens from the Mexican workers tested.

Current knowledge and thinking about State agency planning for community mental health services are examined.

State Agency Program Planning for Community Mental Health

CHARLES F. MITCHELL, M.A.

IN SPITE of the rapid advance of community mental health services, the dominant theme at national and regional meetings of State mental health personnel is still largely mental hospitals and mental patients. Yet severe mental illness is such a small part of the total picture that it seems important to look at the whole range of mental health needs and services.

The latest available estimates indicate that about 10 percent of the population of the United States have significant mental health problems, but only 0.6 percent are ill enough to require care in a psychiatric hospital (1, 2). The other 90 percent, the so-called normal group, need mental health education and counseling services to help prevent the development of disabling mental illness. In planning programs for community mental health services we have to look at the entire spectrum and visualize all potential needs.

About 10 years ago, in the early stages of community mental health planning, it all seemed pretty simple to us in State mental

health agencies. First, we were supposed to develop further the existing mental health clinics and to start new clinics as rapidly as possible. There was little question as to what kind of clinics they should be. Second, we were supposed to set up an educational program, consisting of talks, workshops, films, and pamphlets, aimed at whatever groups seemed to be interested.

Now we are not quite so glib in discussing or plunging into these activities. We do more systematic and down-to-earth planning, and we use criteria for program selection. But we need to reexamine these criteria frequently and look at the assumptions and principles that underlie them.

Current Assumptions

These are the current assumptions that influence our planning:

★ Two attitudes seem to predominate among those persons who are concerned in some way with community mental health programs. One is the extreme optimism reflected in the idea that "mental health is all," a sort of cultist mental health movement. The other is a pessimistic attitude that "this preventive stuff" is all a nice frill, but "you can't prove that it prevents anything and it is not a real program like some others, and not nearly as important as taking care of the acutely mentally ill."

Mr. Mitchell has been with the Texas State Department of Health for 10 years and director of the division of mental health for 7. The article is based on a talk given at the regional workshop for State-level mental health program personnel held by the Community Services Branch, National Institute of Mental Health, Public Health Service, at Brighton, Utah, April 21-25, 1958.

Somehow we have to find a middle ground and recognize the climate of public opinion in which we have to operate.

- ★ Community mental health programs in most States are going to be small for a long time, because no large appropriations will be made until we have specific preventive methods that are more definitely proved. Moreover, there are not likely to be pressure groups available, such as the councils for the mentally retarded, to get funds for our programs. We don't have an organization of relatives of the neurotic who are going to work with State legislatures to get funds.

- ★ The number of professional mental health personnel will not greatly increase in the next 5 to 10 years.

- ★ No one type of program will do the job, nor is it possible to carry out all of the potentially productive community mental health activities.

- ★ Mental health associations and other lay groups are already carrying on educational programs, some of them in community mental health. Such programs are likely to increase further in both number and scope in the future.

- ★ Many nonmental health professional persons and agencies already perform various community mental health functions. They have varying degrees of awareness of their actual and potential roles. These people and agencies can be aided through consultation and organizational measures to do a much more effective and comprehensive job. Some already are seeking such help.

- ★ Existing mental health clinics are not being fully utilized. For example, the recent study of the Los Angeles Child Guidance Clinic showed that nearly 80 percent of the cases seen in 1 year could have been treated just as well or better by other local agencies or by private practitioners (2). In addition, it seems obvious that clinics can do much more consultative and educational work with other agencies and practitioners and can relate their traditional services more directly and meaningfully to those of other agencies.

- ★ Psychiatric services in general hospitals are growing rapidly in number, size, and function. It is an open question how well such services are currently integrated into local and

State patterns of community mental health services.

- ★ Local policymaking and control are essential for long-range, permanent growth of community mental health services, if the services are to endure. State control and operation tend to inhibit local growth and participation. Of course, this assumption is affected by State and local traditions and the geography and economy of a particular State.

- ★ State agency planning for local mental health services must take into account local experience and the attitudes and methods traditionally used in other civic projects. Hunter has highlighted the importance of local power structures in this connection (4, 5).

- ★ The nature of the State program for community mental health will be markedly affected by its parent agency and the value systems of the particular professional disciplines on the staffs of the State program and the parent agency.

Principles and Basic Questions

The State agency obviously must accept the dual responsibility of developing further existing patterns of service and of initiating projects which test different combinations of approaches to preventive services in mental health while evaluating the effectiveness of both the old and the new.

Selecting preventive program areas is difficult. We need activities which are tangible, dramatic, convincing, and based directly on need. We cannot continue indefinitely on faith or on the basis of testimonial evidence that we are doing something that justifies our use of the taxpayer's dollar.

Also we are recognizing more clearly that clinics are expensive and that they alone cannot meet all the mental health needs of the community. Clinics provide an essential service, but perhaps should be thought of as a springboard for other activities.

It seems helpful to categorize the kinds of possible activities according to four levels of prevention so that we get some idea of the scatter of our various activities among these levels.

Level 1 prevention consists of building and

State Agency Program Planning for Community Mental Health

CHARLES F. MITCHELL, M.A.

IN SPITE of the rapid advance of community mental health services, the dominant theme at national and regional meetings of State mental health personnel is still largely mental hospitals and mental patients. Yet severe mental illness is such a small part of the total picture that it seems important to look at the whole range of mental health needs and services.

The latest available estimates indicate that about 10 percent of the population of the United States have significant mental health problems, but only 0.6 percent are ill enough to require care in a psychiatric hospital (1, 2). The other 90 percent, the so-called normal group, need mental health education and counseling services to help prevent the development of disabling mental illness. In planning programs for community mental health services we have to look at the entire spectrum and visualize all potential needs.

About 10 years ago, in the early stages of community mental health planning, it all seemed pretty simple to us in State mental

health agencies. First, we were supposed to develop further the existing mental health clinics and to start new clinics as rapidly as possible. There was little question as to what kind of clinics they should be. Second, we were supposed to set up an educational program, consisting of talks, workshops, films, and pamphlets, aimed at whatever groups seemed to be interested.

Now we are not quite so glib in discussing or plunging into these activities. We do more systematic and down-to-earth planning, and we use criteria for program selection. But we need to reexamine these criteria frequently and look at the assumptions and principles that underlie them.

Current Assumptions

These are the current assumptions that influence our planning:

★ Two attitudes seem to predominate among those persons who are concerned in some way with community mental health programs. One is the extreme optimism reflected in the idea that "mental health is all," a sort of cultist mental health movement. The other is a pessimistic attitude that "this preventive stuff" is all a nice frill, but "you can't prove that it prevents anything and it is not a real program like some others, and not nearly as important as taking care of the acutely mentally ill."

Mr. Mitchell has been with the Texas State Department of Health for 10 years and director of the division of mental health for 7. The article is based on a talk given at the regional workshop for State-level mental health program personnel held by the Community Services Branch, National Institute of Mental Health, Public Health Service, at Brighton, Utah, April 21-25, 1958.

potential in community mental health. Perhaps the most important task of the State agencies is to convey a spirit of experimentation and evaluation of diagnostic and treatment functions to the clinics and the psychiatric services of the general hospital.

Perhaps we can, to some extent, motivate clinic directors, boards, and staffs to reexamine traditional procedures, such as the handling of waiting lists, diagnostic procedures, treatment methods, preventing dropouts of patients, followthrough of treated patients with referrals to other agencies, and followup studies of patients already seen.

Another goal might be to encourage existing clinics to devote more staff time to consultation, education, and community organization functions. Perhaps we should insist that new clinics devote a certain portion of staff time to these functions in addition to diagnostic and treatment services.

Clinicians in general are increasingly aware of their potential contribution to and of the value of such activities, but to what extent are they able to perform consultation and education functions? Should we encourage the clinics to serve as a hub for all community mental health activities? Can we expect them to do this without special training for their staffs? And should the State agency provide scholarships for advanced training to help clinic staffs carry out new methods of service to the community? Where can one get such training? Perhaps the State agency should attempt to provide it.

Another question concerns existing services. What are the disadvantages and advantages of written agreements if financial aid is provided to the clinics? Is it sound to use such agreements as a basis for periodic discussions of the clinic's program and function? Few persons would argue that the State agency should not set some standards, particularly for personnel. It is surely appropriate to encourage the clinic to use State agency staff in a consultative capacity, both in basic administration and in various specialized clinic functions.

In a number of States, statewide workshops on a variety of topics or inservice training programs for staffs have been undertaken with considerable success.

The recently developed statistical reporting system for psychiatric outpatient clinics provides an opportunity for an overview of clinic services. In Texas we found that having our annual workshop of psychiatric clinic staffs immediately following the publication of the annual statistical report seemed to stimulate clinic staff thinking and resulted in productive discussion.

Developing New Services

New services can be divided into those which are initiated by the State mental health agency, those initiated by another State agency, and those initiated locally. This is an arbitrary grouping, and any of the following kinds of services could be initiated by any one of the three sources, but in our experience this grouping seems reasonable.

At the present time we are convinced that four professional groups, physicians, nurses, teachers, and clergy, are in a strategic position to foster the mental health of the people they serve. What is the State mental health agency's responsibility to them? Should we at least be aware of the extent to which the schools of medicine and nursing, the teachers colleges, and theological seminaries include in their regular curriculums indoctrination and training in concepts and methods in community mental health? The National Institute of Mental Health, Public Health Service, is providing grants to schools of nursing, among others, for this purpose. But it is our experience that the professional schools want to know how to integrate community mental health into their curriculums and how to relate this to professional practices in the State as a whole.

Another kind of new project, mentioned previously, might consist of detecting early cases of emotional or personality disturbance in gifted children and providing prompt treatment for them and their families. The State agency might initiate this service in one or more school systems and test it for several years. Such a program should be set up to encourage continuation by the schools following completion of the pilot project.

Many States have services for expectant

maintaining mental health through programs that teach the best current knowledge and the best methods of fostering healthy parent-child relationships and human relationships generally.

Level 2 includes all the activities carried out by the nonmental health professional people in private practice or as staff of health, welfare, and education agencies. The physician, nurse, teacher, social worker, clergyman—all those in a “caretaking” capacity in the community—can do early casefinding and provide counseling and guidance to individuals, particularly children, showing symptoms of emotional disturbance.

In this level, we are inclined to overlook the significance of the clergy. A public opinion study done in Louisville, Ky., a few years ago showed that people turn most frequently to their clergyman when they have problems.

Level 3 prevention consists of services provided in clinics, primarily diagnosis and treatment of moderate emotional disturbances.

Level 4 consists of services in general hospitals for the acutely ill psychiatric patient, as well as rehabilitation of mental hospital patients who have returned to the community.

Probably the major dilemma in program planning is where to begin in the whole spectrum of possible services. Should we try to improve the mental health of the entire population, or concentrate on the 6 percent of the families who have a high incidence of social and emotional disorders?

A promising approach is to focus on populations at risk. Schwartz lists nine groups worthy of concentrated efforts in community mental health (6):

1. Juvenile delinquents. For his purpose Schwartz limits this category to delinquents whose parents have been in trouble with the law.

2. Persons who have attempted suicide.

3. Those in urban areas where the rate of incidence for mental illness is high.

4. Expectant mothers who need help in preventing organic damage to the unborn child and in emotional problems.

5. Children under 3 years of age who are physically and emotionally deprived of mothering (7).

6. Families on relief.

7. Bereaved persons who need help in handling their “grief work,” as described by Lindemann (8).

8. The acutely psychiatrically ill. Psychiatrists and other mental health staff can provide emergency services at home to prevent hospitalization. Successful programs of this kind have been carried out in Amsterdam in the Netherlands and in Philadelphia, Pa.

9. Persons who are slated for promotion to positions at a higher level. This group has a high incidence of problems.

Another approach, advocated by Caplan of the Harvard School of Public Health, is to center efforts on the crisis periods in people's lives when they are most amenable to changes in basic attitudes (9).

Certainly we must compromise in considering the direction and the distribution of mental health activities. For example, if we can conduct only two special demonstration projects during a given period, probably it would be a good idea to work with one group in which the risk is not commonly recognized, such as gifted children. The other might focus on a group, such as aged persons in nursing homes, whose actual or potential mental health problems are apparent to most people.

Should we try to provide services to all geographic areas of the State? We might provide educational materials to the entire State; then, in a few areas, set up projects as demonstrations and encourage other communities to emulate those which appeal to them.

Another question is whether to move into communities that do not request services. When there are epidemics or excessive mortality or morbidity rates, public health teams traditionally have moved in without waiting for an invitation. Yet most of us question whether permanent gains in community health are made without local initiative and local assumption of responsibility and leadership. How long do we wait before we approach a community which requests no services but has obvious and critical needs?

Developing Existing Services

In considering existing patterns of services, probably nobody claims that the mental health clinics at present are working at their maximum

often initiated by other agencies are teaching child development, parent-child relationships, and other topics through study groups such as those sponsored by local mental health associations. Another such program carried out by many universities is mental health inservice education, consultation, and similar services to agency staffs such as public health nurses, teachers, and other professional persons.

A broad new area that seems to be commanding a lot of attention is accident prevention, as exemplified by the special psychiatric project in Detroit, where persons who have second accidents involving drinking are required to have a psychiatric evaluation (12). In this way an effort is made to find the accident-prone or the severely disturbed persons, and a frightening number of people have been discovered who have really severe personality disorders.

We need to encourage the various agencies to take more and more responsibility for continuing all these projects. We are kidding ourselves if we think we can do the whole job. We can only serve as stimulators, collaborators, and helpers.

Any of the activities previously listed could also be initiated by a local agency or planning group. We have to consider the particular situation in any given State to determine whether such locally initiated services should be organized on a local, regional, or statewide basis. But wherever a project is set up and whoever initiates it, it does seem appropriate for the State agency to provide consultation in helping to define and clarify the problem which prompted the request for service. The extent to which we continue to help define the problem or engage actively in planning, organizing, and operating a project depends on the whole constellation of services that we are trying to carry out and the role we have assumed as a State agency.

Since we cannot cover the whole State with intensive services, we need to consider how best to undertake at least one or two demonstration projects in local areas. Before initiating such demonstrations, there must be a readiness in the community for the project and involvement of citizen leaders, and the project must have the potential for a long-term contribution to the broad objectives of the State program, as well

as to the immediate local situation. Such new projects may demonstrate a new kind of service, a new pattern of services, or a different application of existing services.

We think in the Texas program that probably the most important component of such a project is a built-in system of data recording for evaluation at the end of the project. Projects seem to require at least a full year of advance planning and, based on our experience during the last 4 years, at least 5 years of operation to accomplish lasting and convincing results.

In planning for a local project, staff must be adequate to meet the local demands for service, to handle community organization and interpretation activities, and to do the research work, including the project report. Such projects, we find, quickly generate more demands for service than the staff can handle, and it is extremely important to have sufficient staff, particularly persons assigned primarily to the research phases. The project might be aided either by a financial grant from the State agency or by lending a State agency staff member.

Policymaking, however, should be a function of a local representative group. We have used a written agreement in such projects, and have found it is valuable as a means of clearly defining the responsibilities of the two parties involved. If a community council exists, the new project should be developed by working in cooperation with and sometimes through it.

A staff development and training component is needed to develop the type of State community mental health program I have described. For many years most States have provided scholarships for the various mental health disciplines and have found this practice an effective method of recruitment. But as community mental health services move into untested kinds of program activities, the existing staff and the staff that is added as programs grow will need advanced training.

We think it is very important to work cooperatively with existing clinics and other psychiatric services and with universities and training centers to develop more training facilities within the State. If this is not feasible, regional agreements, similar to those developed by the Southern Regional Education Board,

mothers through maternity clinics and for mothers and children in well-child clinics. Frequently such services have been initiated locally or through the maternal and child health programs. But what is the responsibility of the State mental health agency for seeing that the potentials of these services are utilized throughout the State?

More adequate interagency services to disorganized families are seldom initiated locally or by another State agency. The studies of Community Research Associates in St. Paul, Minn., (10) and elsewhere indicate that a small proportion of families produce a great proportion of the behavior and personality disorders as well as other problems in a given community. Few would question the assertion that community health, welfare, and education agencies are not collaborating extensively in making comprehensive family diagnoses, for example, or in providing long-term, integrated services to such families. Should the State mental health agency initiate and help plan such collaboration? Perhaps the State agency should at least initiate local conferences or studies on the maximum use of mental health clinics by local agencies.

The State agency might also initiate an epidemiological study of the incidence of various kinds of mental illnesses. A very modest study (11) we did recently revealed that of first admissions to mental hospitals, almost half of the patients and their families had been known to one or more local agencies within a 3-year period immediately prior to hospitalization. Such a study can generate local projects in level 4 prevention which involve systematic interagency collaboration and stimulate the setting up of a system of psychiatric consultation and other supplementary services to the agencies serving these families. Such services would help the agencies to stabilize the family, prevent illness which would require hospital care, and perhaps result in long-time rehabilitation of some families.
